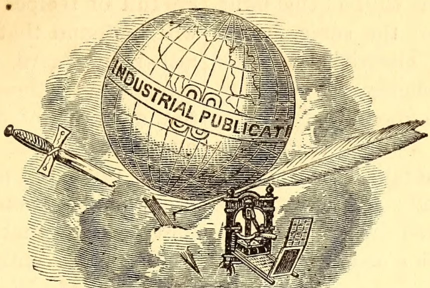
SCIENCE IS KNOWLEDGE.



KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

VOL. I. NEW YORK, JANUARY, 1878. No. 1.

Make-shift Apparatus—Its Successes and Failures.

THE majority of our text-books and books on popular science delight to tell us of the wonderful scientific discoveries which have been made by means of very cheap and simple apparatus. We are told how Newton investigated the laws of light and color by means of soap-bubbles—the emblematic plaything of children; how Black discovered latent heat by means of a few thermometers and old dish-pans; how illuminating gas and its applications were discovered by Murdoch, who used the bowl of a tobacco pipe for his retort, and the stem for the first main; how Franklin discovered the identity of lightning and electricity by means of a boy's kite, and dozens of other cases. All these instances afford example and encouragement to those who are trying, with limited means, to see for themselves the great wonders of nature, but they are sometimes liable to mislead those who are inclined to think that if Galileo, by means of a telescope which was little better than a modern spy-glass, made discoveries which have immortalized his name, it is not worth while for them either to procure costly apparatus or to spend great labor in finishing and perfecting that which they make themselves. To some persons the idea of "rough and ready" possesses wondrous charms, and they come at length to despise the neatness and care which are born of accuracy and delicacy, and without which no scientific work really worthy of the name can be accomplished.

In this connection two things must be borne in mind. In the first place, we must remember that if Newton made great discoveries with very insignificant apparatus, it required a Newton to do it; and in the second place, the extent to which such discoveries can be carried, even by Newton, are quite limited. When Newton pushed

his discoveries in regard to the colors of very thin films beyond the first steps, it taxed the utmost skill of the London opticians to supply him with lenses sufficiently accurate for his purpose. Franklin determined by means of a kite the fact that lightning and electricity are the same, but to investigate the laws of electricity requires apparatus of extreme delicacy and accuracy. Galileo discovered the moons of Jupiter with a telescope no better than that which any smart boy might construct for himself—lenses and all; to discover the moons of Mars demanded the aid of a telescope which it required a master hand to produce.

We hope our young friends will ponder these facts, and not be discouraged because they fail to accomplish, with inferior apparatus and tools, things which can be done only with the very best appliances. Neither should they be discouraged because they do not at first succeed in using their tools with the ease and skill which older hands have acquired. It is wonderful how far the skill which comes of long practice will carry one. And although good workmen generally have good tools, yet how often do we see an experienced hand accomplishing wonders with very inferior means? It is rare that a person of moderate experience can perform an experiment successfully at the first trial.

On the other hand, those who are compelled, by choice or necessity, to use make shift apparatus, should feel diffident in regard to the importance and truth of any discoveries that they may make until these discoveries have been confirmed by more careful investigation, undertaken with more perfect appliances. In this connection it will be well to bear in mind the saying of a noted scientist, who, after listening to the praises of a young man who was said to have made some very wonderful discoveries with very inferior apparatus, exclaimed: "Sir, it was not *in spite* of the badness of his apparatus that he made these supposed discoveries, but *in consequence* of it."

General Rules to be Observed in Using Cements.

SO much has been written concerning different cements, that our periodicals are full of recipes on this subject. But it will be found that the information given is rather in regard to the materials used in compounding these cements than in regard to the manner of using them, while it is unquestionably true that quite as much depends upon the manner in which a cement is applied, as upon the cement itself. The best cement that ever was compounded would prove entirely worthless if improperly applied. We have hundreds of recipes for glues, pastes and cements of different kinds, and yet the public is constantly on the *qui vive* for new ones, and no more acceptable recipe can be sent to our popular scientific and technical journals than one for a new cement. Now, the truth is, that we have cements which answer every reasonable demand, when they are properly prepared and properly used. Good common glue will unite two pieces of wood so firmly that the fibres will part from each other rather than from the cementing material; two pieces of glass can be so joined that they will part anywhere rather than on the line of union; glass can be united to metal, metal to metal, stone to stone, and all so strongly that the joint will certainly not be the weakest part of the resulting mass. What are the rules to be observed in effecting this?

The first point that demands attention is to bring the cement itself into intimate contact with the surface to be united. Thus when glue is employed the surface should be made so warm that the melted glue will not be chilled before it has time to effect a thorough adhesion. The same is more eminently true in regard to cements that are used in a fused state, such as mixtures of resin, shellac and similar materials. These matters will not adhere to any substance unless the latter has been heated to nearly or quite the fusing point of the cement used. This fact was quite familiar to those

who used sealing-wax in the old days of seals and twenty cent postage. When the seal was used rapidly, so as to become heated, the sealing-wax stuck to it with a firmness that was annoying, so much so that the impression was in general destroyed, from the simple fact that the sealing-wax would rather part in its own substance than at the point of adhesion to the stamp. Sealing wax or ordinary electrical cement is a very good agent for uniting metal to glass or stone, provided the masses to be united are made so hot as to fuse the cement, but if the cement be applied to them while they are cold it will not stick at all. This fact is well known to the itinerant venders of cement for uniting earthenware. By heating two pieces of delf so that they will fuse shellac, they are able to smear them with a little of this gum, and join them so that they will break at any other part rather than along the line of union. But although people constantly see the operation performed, and buy liberally of the cement, it will be found that in nine cases out of ten the cement proves worthless in the hands of the purchasers, simply because they do not know how to use it. They are afraid to heat a delicate glass or porcelain vessel to a sufficient degree, and they are apt to use too much of the material, and the result is a failure.

The great obstacles to the absolute contact of any two surfaces, are air and dirt. The former is universally present, the latter is due to accident or carelessness. All surfaces are covered with a thin adhering layer of air, which it is difficult to remove, and which, although it may at first sight seem improbable, bears to the outer surface of most bodies a relation different from that maintained by the air a few lines away, and until this layer or film of air has been removed it prevents the absolute contact of any other substance. The reality of the existence of this adhering layer of air is well known to all who are familiar with electrotype manipulation, and it is also seen in the case of highly polished metals, which may be immersed in water without becoming wet. Thus the surface of a needle retains this film of air so strongly that it will float on the surface of water rather than give it up. So, too, a drop of melted glue allowed to simply fall on a surface of dry, cold wood and solidify there, will often fail to adhere at all, while if the same drop had been rubbed in, it would have attached itself to it with wonderful power of adhesion. What is true of glue is true of almost every other cement, and unless this adhering layer of air is displaced, it will be impossible for any cement to adhere to the surface to which it is applied, simply because it can not come into contact with it.

The most efficient agents in displacing this air are heat and pressure. Metals warmed to a point a little above 200°, become instantly and completely wet when immersed in water. Hence for cements that are used in a fused condition, heat is the most efficient means of bringing them in contact with the surfaces to which they are to be applied. In the case of glue, the adhesion is best attained by moderate pressure and friction. When it is intended to unite two pieces of earthenware or glass together, or a piece of glass or other substance to metal, by means of a cement that is to be used in a fused state, the surfaces that are to be united should always be made so hot that the cement will become perfectly liquid while in contact with them.

To be continued.

College Workshops.

REFERRING to the fact that the liquefaction of oxygen, recently accomplished by MM. Pictet & Cailletet, has been within the reach of English scientific workers for years, *Nature* makes the following pungent remarks: "It is also clear that to cope with modern requirements our laboratories must no longer contain merely an antiquated air-pump, a Leyden jar, and a few bottles, as many of them do. The professor should be in charge of a work-shop, instead of an old curiosity shop, and the scale of his operations must be large if he is to march with the times."

Our Aims.

SCIENCE in its various applications is daily becoming more and more an element, not only of the education of our people, but of their everyday thought. But while it forms the most important element of the education of our modern schools, there are many persons outside of these institutions who have a taste for scientific culture, but who have neither the time nor the training required to enable them to attack ponderous text-books without a teacher, and yet who would like to acquaint themselves with the new developments of science, as well as with the new applications of old principles, provided these were presented in simple and concise form. Such persons have no time to study the larger periodicals, and from want of previous culture they often fail to understand them. As for the "Science Columns" of our political, literary and religious journals, the information they contain is too fragmentary to fill the requirements we have indicated.

In intimate connection with this well-recognized want, there is another, the supply of which we propose to make a prominent feature of our journal. It is characteristic of young Americans that they want to be DOING something. They are not content with merely *knowing* how things are done, or even with *seeing* them done; they want to do them themselves. In other words, they want to experiment. Hence the wonderful demand that has sprung up for small tool chests, turning lathes, scroll saws, wood carving tools, telegraphs, model steam engines, microscopes and all kinds of apparatus. In nine cases out of ten, however, the young workman finds it difficult to learn how to use his tools or apparatus after he has got them. It is true that we have a large number of very excellent text-books, but these are not just the thing. What is wanted is a living teacher. Where a living teacher cannot be found, the next best thing is a live journal, and this we propose to furnish. And in attempting this it is not our intention to confine ourselves to mere practical directions. In these days of knowledge and scientific culture, the "Why" becomes as necessary as the "How." We therefore propose to give clear and simple explanations of the principles involved in the various mechanical and chemical processes which we shall undertake to describe.

We have commenced this journal on a small scale for very obvious reasons. A journal of this kind is a novelty, and we do not wish any one to give up any of their present sources of reading for the sake of adopting this one. The low price of the YOUNG SCIENTIST, and the slight demand which it makes upon the leisure of its readers avoids this difficulty.

So much for the general character of the objects which we have in view. Our plans, in detail, will be found in our prospectus.

Aiding the Swindlers.

WHEN a swindling concern can get their wares puffed into notice by articles in the "Scientific" columns of our popular papers, they are almost certain to attain the end at which they aim. The following humbug has been exposed over and over again, but it is caught up every now and then by some of the hack writers of "Science Columns," and a new lease of life given to it. We clip from a recent issue of a popular monthly journal:

"Quite a notable industry is now carried on in Paris, namely, the manufacture of what are termed veneered diamonds, the method of production being briefly, according to the following fashion: The body of the 'gem' is of quartz, or crystal, this being considered the hardest and best

adapted substance that can be made available for the purpose. Then, after the crystals are cut in proper shape, they are put into a galvanic battery, which coats them over with a liquid, this latter being made of diamonds which are too small to be cut, and of the clippings and cuttings that are taken off of diamonds during the process of shaping them. In this way, all the small particles of diamonds that have heretofore been regarded as comparatively worthless, can now, by means of this ingenious French process, be made quite serviceable in the jeweller's art."

Every statement in this paragraph is false. Any such working over of small particles of diamonds is, in the present state of our knowledge, an impossibility. Stones which pretend to be thus veneered are, however, largely sold, and the swindle is assisted by journals which publish, without comment, paragraphs like that just quoted.

Liquefaction of Oxygen.

OUR scientific exchanges come to us with the announcement that M. Pictet has succeeded in liquefying oxygen. If this be true, it is unquestionably the most important scientific feat of the year 1877.

We must confess, however, that we have our doubts as to the truth of the statement, and for these reasons: In the first place all the accounts that we have seen are far from intelligible, but so far as they do convey clear ideas of the process, it would seem that oxygen, under a pressure of 4,800 pounds to the square inch, has been subjected to a temperature of 140° below zero (centigrade). The pressure of the oxygen was obtained by *generation;* that is, a given quantity of material capable of producing oxygen was placed in a retort capable of withstanding a pressure of 12,000 pounds per square inch, and when the gas was liberated, it produced the pressure stated (4,800 pounds per square inch) as there was no escape for it. The cold was produced by the evaporation of solid carbonic acid previously cooled by means of liquefied sulphurous acid. Now, all this has been done before, and to an enormously greater extent than is claimed by M. Pictet. Years ago Faraday produced a temperature of 110° C., by exposing a mixture of solid carbonic acid and ether to a vacuum. Natterer, by the use of bisulphide of carbon, instead of ether, in the above mixture, obtained a temperature of 140° C.

As to pressure; a pressure of 4,800 pounds per square inch has been but a trifle these many years, and might at any time have been obtained with a single acting pump of good construction operated by hand. By means of a *series* of pumps, Natterer obtained a pressure of nearly three thousand atmospheres! (See Cooke's "Chemical Physics," pages 299 and 600.) To nearly this temperature and pressure did he subject oxygen, and yet he failed to liquefy it.

The discrepancy here is so great that we feel there must be an error somewhere. Even if Natterer's estimates were too high, it is scarcely possible that he could have gone so far astray as to believe that he had nearly ten times the pressure that he had. On the other hand, it is unlikely that M. Pictet could have so greatly underestimated his temperatures and pressures; and it is still more unlikely that oxygen which has resisted 40,000 pounds per inch, and —140°, should yield to 4,800 pounds per inch and —140°. We are therefore afraid that M. Pictet has deceived himself, and that some impurity, or something similar, has been mistaken for the liquefied oxygen. We should, however, be glad to know that he has really accomplished this wonderful feat.

Since writing the above, further accounts, giving more minute details, have reached us, and although the evidence in favor of the fact is not to our minds conclusive, we must admit that since such men as Berthelot, Sainte-Claire Deville, Boussingault, Mascart and others, men of great experience in experimentation, have accepted the feat as accomplished, it is probable that the claims of MM. Cailletet & Pictet are well founded. But if so, the curious fact remains to be explained, that, with abundant means at their command, physicists have for years failed to accomplish the same thing.

Correspondence.

Information Wanted.

1. *Ed. Young Scientist*—Your prospectus having fallen into my hands, I see that you propose to bring your subscribers into communication with each other. I am very glad of this, for I find that when I write to make an inquiry of some papers, the editors just turn to some old receipt book and copy out of that, and ten to one the thing will not work, for, like the razors Peter Pindar tells us about, too many of the recipes that we find in "encyclopædias," and "dictionaries of recipes," were made to sell and not to be put in practice. A better plan is that which you have adopted, which is to open an exchange for the barter of ideas, for as some one says, "Everybody knows more than anybody."

So much by way of preface. Can any of your readers give me a really good method for "ebonizing" wood? I have several recipes, but none of them give good results. A recipe recently published in a prominent journal would not work at all. AMATEUR.

2. *Ed. Young Scientist*—Seeing by the circular announcing your journal, that you propose to insert letters from subscribers who desire information, I would ask if any of your readers can tell me how to repolish the brasswork of a telescope that has been in use for some time, and has become quite tarnished? I have used very fine polishing powders, but although this answers well for a few days, in a short time the instrument looks worse than ever.

RUSTYCUSS.

Laboratory & Workshop

[Specially written for the YOUNG SCIENTIST.]

The Art of Sharpening Edge Tools.

BY JOSHUA ROSE, M. E.

NO. I.

There is an adage which tells us that "a good workman never quarrels with his tools." And this is too often supposed to mean that we can make up for a defect in a tool by the employment of a little extra skill and care in its handling. A more correct interpretation, however, seems to be that a good workman so shapes and sharpens his tools that there is no need to quarrel with them, for in a tool made for any purpose there can be no fault that does not lie at the door of its maker or user, and we shall find that with tools, as with everything else, they are good servants in proportion as they are properly cared for and used.

The construction of every tool that the human hand can use is governed, both as to shape, strength, and the form of its cutting edge, by principles easily applied when properly understood, and to explain in a simple manner these principles and their application will be the object of these articles.

Beginning, then, with the common penknife, we have a tool which may be used either to cut, split or scrape; but since its duty is mainly that of cutting, its edge should be formed with a view to that end, thus fitting it to the largest class of work. This will, fortunately, not incapacitate it for the performance of its lesser fields of usefulness.

The shape of a penknife blade is in section that of a wedge, and the sharpness or keenness of its cutting edge depends upon the acuteness of the wedge, and upon how nearly we can make the two sides or facets at the thin end of the wedge meet, without either facet turning over towards the other at the extreme edge, and how smooth and even we can leave the facets at the edge. The difficulty experienced in accomplishing this is due to the weakness of the metal, which causes it to bend over and away from the surface applied to the instrument used for sharpening or abrading it. The acuteness of the wedge, in a new knife, is fixed by the manufacturer; hence we need not at present discuss it, but may pass at once to the sharpening processes.

If we grind a knife blade upon a grindstone, and then put it under a microscope, we shall find that it appears as shown in Fig. 1. The marks shown upon the facet are due to the fact that the cutting or abrasion performed by the grindstone or emery wheel, is done by the corners or angles of the grains of emery or stone, as the case may be, and it follows that the coarser those grains, and the harder the blade is pressed to the stone or wheel, the deeper, within certain limits, will these marks be. The blade is supposed, in Fig. 1, to have been held upon the stone with the plane of revolution of the latter at a right angle to the length of the blade, as denoted by the line A B, hence the fine teeth at the edge stand also at a right angle to the blade. If the length of the blade is held at an angle to the stone, the marks and the teeth upon the edge will stand at a corresponding angle, as shown in Fig. 2, in which the marks represent the plane of revolution of the grindstone. Suppose, then,

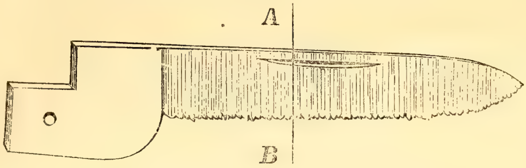

Fig. 1.

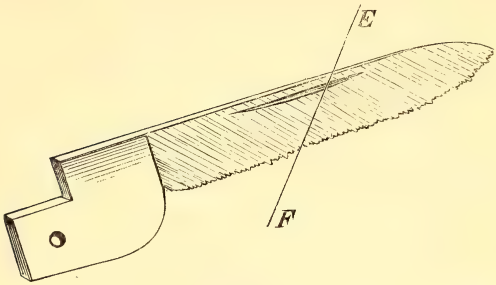

Fig. 2.

EDGE OF NEWLY-GROUND KNIFE, AS SEEN UNDER THE MICROSCOPE.

that we were to hold one side of the blade to the stone, in the position shown in Fig, 2, with the plane of revolution of the stone as denoted by the marks, and the other side with the plane of revolution in the direction denoted in the same figure by the line E F; then the marks on the facets and the indents at the edge will cross one another, leaving it less ragged than would be the case if both sides were ground as in Fig. 1, and since smoothness at the edge is desirable, we have arrived at the best position in which to hold the blade upon the stone.

If, after having ground the two faces, in either position, we put the blade under a microscope, we shall find that it appears as shown in Fig. 3, the edge being elongated beyond its natural length and turned to one side. The reason of this is that the metal, being weak, bends and gives way to the pressure, turning away from the face that is in contact with the stone, and it is obvious that the greater the pressure with which the blade is pressed to the stone, the more the metal will bend away.

Fig. 3.

It follows therefore that though the blade may be pressed firmly to the stone during the early part of the grinding, so as to remove the surplus metal as quickly as possible, it should be held lightly during the latter part, to avoid, as far as is practicable, the formation of this undesirable web, which is termed a *feather* edge, because of its weakness and ragged appearance. As soon as the knife edge is put to cutting duty, the feather edge breaks off, leaving a flat place at the thin end of the wedge, and to that extent impairing its sharpness. At what precise depth it will break off depends upon the pressure applied and the direction in which it is applied; but as a rule the harder the pressure, the deeper it will break off, and hence the more it will impair the edge. One of the best methods of removing it is to draw it lightly across a piece of soft wood, first lengthways and then across the grain.

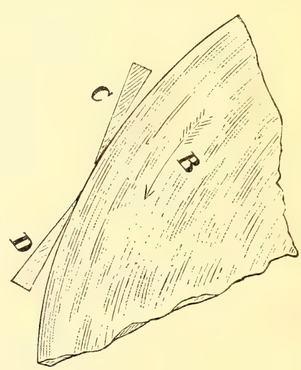

Fig. 4.

Another consideration now presents itself, for we find that the position in which the workman stands with regard to the stone has an important bearing upon the amount of feather edge that will be formed. Suppose, for instance, that Fig. 4 represents a section of a grindstone running in the direction of the arrow B, and that C and D represent sections of two knife blades; then C would have a long feather edge formed upon it, while D would not, and the latter is the best position; but if the stone has any very soft place in it, the blade held in that position is apt to catch, and if the stone is out of true, it is sure to do so more or less, and as it cannot then be held steadily, the face ground will be wavy, and a good edge becomes impossible.

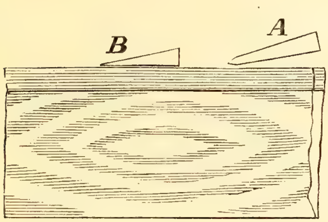

Fig. 6.

To obtain a finer cutting edge, we must have recourse to a finer abrasive, or, in other words, to an oilstone. The action of the oilstone is to smooth the surfaces, and thus remove the feather edge, but while doing this the oilstone itself turns the edge over, forming what is known as a wire edge, which is shown in Fig. 5 at A, which is formed from the causes already explained in referring to the formation of feather edges, and which resembles the feather edge, except that it is smooth, and to a greater extent continuous. In holding the blade to the oilstone, it is necessary to keep the face of the blade level, as at B, Fig. 6, or as nearly so as possible with the oilstone, while at the same time the pressure of the blade is greatest towards the cutting edge.

Fig. 5.

But if the blade has been frequently sharpened upon the oilstone since it was last ground upon a grinding stone, it may be slightly elevated, (as shown considerably exaggerated in Fig. 6 at A), which will give a durable and a moderately sharp edge; but at whatever angle the blade is first held to the face of the oilstone, it should be maintained there, otherwise the action will be to round off the edge. The motion necessary during the oilstoning is shown in Fig. 7, the blades lying diagonally across the stone. The motion of one side of the blade being from A to B, the position at A being shown in full lines, and at B in dotted lines; and of the other side from C to D, at C in full, and at D in dotted lines—the blade being frequently turned over, and the strokes being short and made under light pressure, so as to make the wire edge as small as possible.

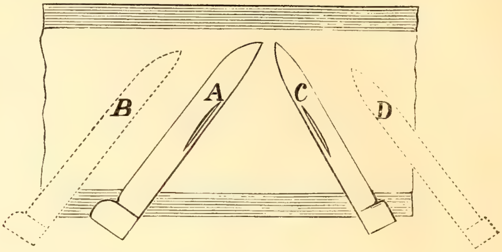

Fig. 7.

Penny Microscopes.

Many years ago a man in London made a living by selling "Penny Microscopes," which would exhibit the eels in paste, the scales on the butterfly's wing, and a few other common objects. Dickens, in his "Household Words," has given a most graphic description of the microscopes, the man and his family, every member of which performed some part toward the production of the little instrument.

These microscopes were made out of small boxes resembling pill boxes, in the lid of which was fixed the lens, while the bottom served to support the object, a hole having been made to allow the light to pass through, so that eels and similar objects might be viewed by holding the box up against the light. The distance between the lid and the bottom was very nearly equal to the focal length of the lens, and might be adjusted by slipping the lid on or off. The interior of the box was of course blackened.

The lens or magnifying power was, of course, a very simple affair. In this case it was nothing more than a drop of balsam of fir placed in a smoothly cut hole about an eighth of an inch in diameter. And yet such a microscope, if skilfully made, would do quite as good work as the brass affairs which are now so commonly sold in the

streets and stores of New York and elsewhere for a dollar.

Wishing to see how much could be done with such a microscope, we made one a few days ago, and tested it. We found that we could see distinctly a great many of the interesting objects about which we read in the books, and although we would not advise any of our readers to depend upon such a microscope for work or study, yet, as it would be a good exercise to make and test one, we will give the way in which we made ours.

We picked out a piece of thin window glass, quite flat and free from specks and air-bubbles. The sharp edges were removed by means of an old file, and the glass carefully washed with washing soda and water, no soap being used. We then took some Canada balsam, or balsam of fir as it is called, and boiled it hard on a second slip of glass. The heat must be moderate, and all bubbles and specks must be removed by means of a pin point. A single bubble in the lens will spoil it. A drop of this clear balsam, made liquid by heat, was placed on the first slip and made as nearly circular as possible. The slip was then laid flat and face downwards to cool and harden, being supported by a small box to keep the balsam free from dust and from contact with anything. The lens was now made. Its action was greatly improved, however, by placing a thin blackened card with a small hole between it and the eye.

A holder for such a lens may be made in a few minutes, with a pocket knife. Ours is shown in the engraving. The handle is simply a piece of wood,

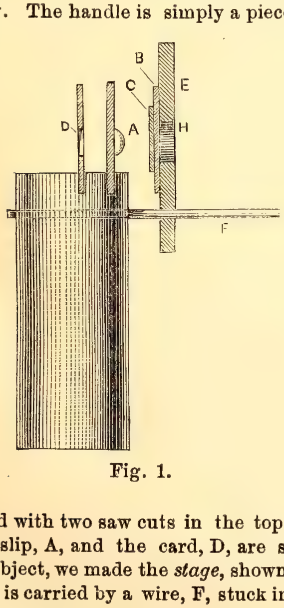

Fig. 1.

round, and with two saw cuts in the top, in which the glass slip, A, and the card, D, are stuck. To hold the object, we made the *stage*, shown in Fig. 2, and which is carried by a wire, F, stuck in the handle. The stage is a piece of wood, with a small hole, F, by which it slides on the wire, and another larger hole, H, to allow the light to pass through the object. Rubber bands, R R, serve to keep in place the glass slip, B, carrying the object. As similar letters refer to like parts in both figures, it will be easy to understand the disposition of the several parts.

After having made it, we went through our cabinet to see what we could do. Finding a piece of trichinous pork, we, with a sharp razor, shaved off a very thin slice (not thicker than tissue paper), which we moistened with glycerine and laid on the

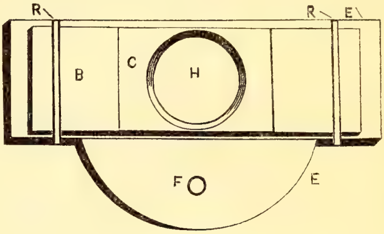

Fig. 2.

glass slip, covering it with a thin scale of mica, (used for stoves, and sometimes called isinglass). We had plenty of thin glass, but wished to use only such things as could be found in any country village. We saw the trichina, or pork worms, beautifully. There they lay coiled up in their *cysts*, or bags, and any one might, by the aid of such an extemporized microscope, have told whether this sample of pork was dangerous or not.

We then took a speck of sour paste, and after mixing it with a little water, placed it on the glass slip, strewed a few short pieces of hair (cut from our own head) amongst it, covered it with mica and examined it. The object of the hairs was to prevent the mica from crushing the eels, and when we have not the regular appliances they should always be used in the examination of animalcules. Seen by our penny microscope, the eels appeared very large and distinct, with their internal organs clearly seen through their transparent skins.

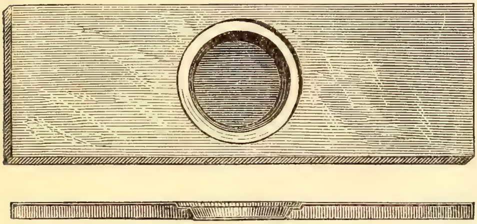
The most beautiful object, however, was the so-called globe animalcule (*volvox globator*). This object can be readily found in most localities in ponds of clear, still water. We have found it in New Jersey during every month in the year. It is too exquisitely beautiful to be described, and our readers should search for it until they find it.

The magnifying power of the microscope we used was about twenty diameters. Great confusion of ideas prevails in the popular mind in regard to magnifying power, and this confusion has been increased by street opticians, who claim "a thousand times" for microscopes which do not magnify as much as the one we have just described. This has produced a reaction the other way, and we have

heard of people who denounced as a fraud an inch lens because it was claimed to magnify ten times! In our next issue we will take up the subject of magnifying power, and the best way to measure it.

A New Slide for Microscopic Objects.

Mr. D. Bryce Scott, Curator of the New York Microscopical Society, has devised a very simple and ingenious slide, by which opaque microscopic objects may be mounted easily, quickly and well. The usual methods, as many of our readers know, is to make a cell on a glass slide—a tedious and comparatively difficult process, when a cell of some



METAL SLIDE FOR OPAQUE OBJECTS.

depth is required. The slide devised by Mr. Scott is of thin sheet metal (brass or tin), and is stamped so as to have a central depression, which forms the cell, and a turned down edge all round it which gives it strength, and causes it to lie steadily on any flat surface. The cell has a ledge, or rebate, as seen in the lower figure, for the purpose of supporting the thin glass cover. When made of tin the whole slide is japanned; those made of brass are lacquered, and the interior of the cell is covered with black asphalt, or some similar dark varnish. The objects are attached to the surface of the varnish by means of gum water, to which a very little glycerine has been added, and the thin glass cover may be cemented down and varnished on the turn-table in the usual manner. The simplicity and efficiency of this slide leads us to believe that it will become a general favorite.

Self-Lighting Lamps.

The well-known property possessed by some forms of platina, whereby it instantly ignites a stream of hydrogen, has long been utilized in the construction of self-lighting lamps. A few years ago these lamps came into great favor as a substitute for matches, from the fact that they were free from the fumes of sulphur, and there was no danger of rats or mice causing unexplained fires. The usual method of forming spongy platina into a mass to be used in igniting hydrogen, is to mix it with fine clay and mould it on a frame work of platinum wire. Platinum sponge prepared in this way is very friable, and must be kept packed in cotton wool when not in use. To get rid of this fragile character, Dr. Hare dipped asbestos, first in a solution of bichloride of platinum, and then in one of sal ammoniac, and found that the asbestos so prepared ignited hydrogen readily. But asbestos is not easily managed. We have succeeded admirably with pumice stone, which we first form into a cylinder of the proper size—say three-eighths of an inch in diameter—and then cut into discs about the twentieth of an inch thick, by means of a fine saw. These discs are soaked for some time in a strong solution of bichloride of platinum in alcohol, and afterwards for an equal period in a solution of sal ammoniac. After being ignited, these discs inflame a jet of hydrogen readily, and we find that they retain their power quite as well as the more delicate forms in common use.

Home-made Telephone.

Prof. Barrett, in a recent lecture on the telephone, gave a receipt for making a cheap one. Take a wooden tooth-powder box, and make a hole about the size of a half-crown in the lid and the bottom. Take a disc of tinned iron, such as can be had from a preserved meat tin, and place it on the outside of the bottom of the box, and fix the cover on the other side of it. Then take a small bar-magnet, place on one end a small cotton or silk reel, and round the reel wind some iron wire, leaving the ends loose. Fix one end of the magnet near, as near as possible without touching, to the disc, and then one part of the telephone is complete. A similar arrangement is needed for the other end. The two are connected by the wire, and with this Prof. Barrett says he has been able to converse at a distance of about 100 yards.—*Nature.*

Scientific Progress.

Lead in Paraffin Oil.—It has recently been found that paraffin oil, which is very similar to our petroleum, is capable of taking up a large percentage of lead.

Poisoned by Cheap Jewelry.—Two young girls in Paris were severely afflicted with sore eyes. Medical aid proved entirely ineffectual, until their cheap ear-rings, which doubtless consisted largely of copper, were removed.

Silk-Worms at Large.—Between San Jose and Santa Clara there are large quantities of silkworms at large. They are understood to be from the old stock of M. Provost. They multiplied on the poplar trees, and then attacked the fruit trees, so so that a fruit grower near by was forced to dose

them with kerosene to save his fruit. They finally gathered on the warm side of a brick building, spinning thousands of cocoons. It would seem from this that the Californians are likely to have an acclimated silk-worm, if nothing more.

Literature vs. Gymnastics.—A Michigan farmer puts it rather suggestively when he writes to the faculty at Yale College: "What are your terms for a year? And does it cost anything extra, if my son wants to learn to read and write as well as to row a boat?"

Nothing but Leaves.—We find in our English exchanges a number of inquiries in regard to the drying and coloring of leaves for ornamental purposes. If an interest should be awakened in this subject, the collecting and exporting of autumn leaves from this country will undoubtedly become a matter of importance. The gorgeous colors of our forest leaves are universally allowed to be unrivaled.

Long-Lived Errors.—The assertion that plants take up whole diatoms and assimilate them, an assertion which was made primarily for the purpose of aiding the sale for manure of the enormous Richmond deposits of fossil infusoria, was thoroughly refuted in the "American Journal of Microscopy," and the refutation was extensively copied into other papers. And yet one of our most popular scientific weeklies reiterates this stupid blunder in a recent issue!

Iron Bird Shot.—It has recently been suggested that iron shot would be better for sporting purposes than lead, and the originator of the idea has elaborated complicated machinery for making the article. His reasons for preferring iron to lead are that shot made of the former metal would keep its shape better, not being liable to get bruised and flattened, either in the pouch or the gun. He does not seem to know that small iron shot would be almost worthless as compared with lead, owing to its lightness. Substitute iron shot for leaden pellets, and you will reduce the range of your gun nearly one-half.

Non-Conductor for High Temperatures.—Mr. Fletcher, of Warrington, England, produces a very perfect non-conductor by mixing one part of ganister or refractory clay and six of sawdust, ramming them in a mould and firing. This makes, after burning, a firm cellular mass, in texture almost like pumice stone, and its power of retaining heat is such that, in this casing, which is only half an inch thick, half a pound of cast iron may be melted, and the furnace, crucible and all, may then be held in the hand without feeling the heat to any considerable extent. The applications of this material are numerous and important. As a jacket for ordinary furnace work, it will prove invaluable in all places except when exposed to mechanical wear. We would suggest that where it is liable to be abraded, a coating of some firmer material be applied. This latter will no doubt conduct heat better, but if protected in this respect by a layer of the new non-conducting material, the loss will be trifling.

The Paris Exhibition.—The buildings of the coming Paris Exhibition in 1878 are the largest yet conceived for the purpose. The nave of the main building is nearly 2,200 feet long; the vista, which includes the two vestibules, is more than 2,360 feet; and each of the transepts and vestibules, more than 1,100 feet. The eight industrial courts are all parallel, and are divided into two series of four each, one series being devoted to the productions of France, and the other to the rest of the exhibiting nations. In the centre of the garden between the two series are two ranges of fine art galleries. On the opposite side of the river is the Trocaden Palace, which is to be devoted to the history of man from the savage state down to the most modern appliances of science and art. It will afterward be used as a municipal museum.

Practical Hints.

Plaster of Paris.—A writer in the "English Mechanic," having occasion to prescribe plaster of Paris as an ingredient for a cement, calls attention to the fact that common plaster, as usually sold in the oil shops, will not do. The plaster used by Italians for making their images is the only kind that will answer. The reason probably is that the latter is sure to be fresh.

Black Finish for Brass.—A writer in the "English Mechanic" gives the following as a good black finish for brass. Make the articles bright, then dip in aqua fortis, which must be thoroughly rinsed off with clean water. Then make the following mixture: Hydrochloric acid, 6 lbs.; sulphate of iron, $\frac{1}{2}$ lb.; white arsenic, $\frac{1}{2}$ lb. Be careful to get all the ingredients pure. Let the articles lie in the mixture till black; take out and dry in hot sawdust, polish with black lead, and lacquer with green lacquer.

Parasites on Canaries.—Almost every one of these household pets is annoyed with little parasites, which render them weak by loss of blood and nervous irritation. To get rid of them we must study their habits. It is a curious fact that these parasites generally feed during the night, and leave the birds during the day. If the cages are provided with hollow perches, they will creep into them, and may be destroyed by boiling water. If the birds like to frequent a nest instead of a perch,

make the nest of something that may be dipped occasionally in boiling water. Half the diseases of cage birds are caused by these almost invisible parasites. Mounted in glycerine jelly, they form very interesting microscopic objects.

A Good Mucilage.—It is said that a mixture of one part of *dry* chloride of calcium, or two parts of the same salt in the *crystallized* form, and thirty-six parts of gum arabic, dissolved in water to a proper consistency, forms a mucilage which holds well, does not crack by drying, and yet does not attract sufficient moisture from the air to become wet in damp weather.

Brass Lacquering.—If you want a good deep gold lacquer, you should make up a small stock bottle, holding, say, half a pint, according to the following recipe; you can then add as much as may be required for the tint you wish to get: Alcohol, ½ pint; dragon's blood, 1 dram; seed lac, 1½ oz.; turmeric, ¼ oz. Shake up well for a week, at intervals of, say, a couple of hours; then allow to settle, and decant the clear lacquer; and if at all dirty, filter through a tuft of cotton wool. Mix with the pale lacquer a day or two before you wish to use it.

Ink that will not Freeze.—Mr. H. A. Sprague, having tried a mixture of alcohol with ink, found that the compound spread and was useless. He then tried glycerine mixed with ink, and found it too thick. Finally he tried a mixture of equal parts of concentrated glycerine, alcohol and water, deeply colored with aniline black. This mixture did not freeze in the coldest weather, it flowed freely from the pen, and did not spread. Our only fear would be that such ink would not dry thoroughly.

Magnifying Power.—Few persons have a clear notion of the magnifying powers that have been or can be obtained by means of the microscope. The following will be found trustworthy: A common hand magnifier, 1 inch focus, magnifies ten times; very strong glasses, twenty times; small globule lenses, such as were sold for 25 cents, about 50 to 75 times; the most powerful single lenses that can be generally used, 150 times; the most powerful single lenses ever found available, 300 times; ordinary compound microscopes, highest power from 250 to 500 times; highest power ordinarily obtained with the best microscopes, 1,500 times; highest power yet obtained, giving fair light and definition, 15,000 to 20,000 times. Claims have been made for much higher powers, but such claims are generally ignored by the best microscopists. By *times* we mean, in all cases, *diameters*. Sidewalk opticians generally mean *areas* when they speak of times. Areas are found by multiplying the diameters by themselves. Ten times, mentioned above, is 100 areas. The cheap microscopes said to magnify 1,000 times, magnify about 33 diameters.

BOOK NOTICES.

A Treatise on Engineering Construction: Embracing Discussions of the Principles Involved, and Descriptions of the Material Employed in Tunnelling, Bridging, Canal and Road Building, etc., etc. By J. E. Shields, C. E. 44 illustrations. New York: D. Van Nostrand.

It would, very evidently, be utterly impracticable to present, in 138 pages, anything like a full statement of the principles involved in the branches of engineering discussed in this book. Between the elements of the subject, however, which are known to every young engineer, and those higher departments of study which are practically valuable only to those professional engineers who make a specialty of certain departments of construction, there lies an important range of applied science, which is of the utmost value to others besides professional engineers. This is the field which Mr. Shields has attempted to occupy, and he has done his work well, giving in clear and concise form just that practical information required in the every day work of the engineer, the builder, the architect, etc. Viewed from this standpoint, the work must be regarded as one of great value to a very large class.

The Gas Consumer's Handy Book. By William Richards, C. E. London and New York: E. & F. N. Spon.

A great deal of the trouble which arises between gas companies and their customers is caused by the ignorance of the latter, and this little book will serve a useful purpose in helping to remove these difficulties, if it should do nothing else. But it will do more than this. It will enable every gas consumer to get the greatest possible amount of good from the gas which he consumes. It will effect this in two ways: first by teaching how to use the article effectively, and, secondly, how to avoid the evil effects which it is apt to produce when burned without proper attention to ventilation and the effect of strong light on the eyes. The work is simple and reliable, and should be in the hands of every householder that uses gas.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge.* Buying and selling must, of course, be carried on in the advertising columns.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a good aquarium, medium size. State what is wanted in exchange. R. H., 8 Beekman Place, New York.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

VOL. I. NEW YORK, FEBRUARY, 1878. No. 2.

General Rules to be Observed in Using Cements.

Concluded from page 3.

ANOTHER very important point is that as little cement as possible should be used. When the united surfaces are separated by a large mass of cement, we have to depend upon the strength of the cement itself, and not upon its adhesion to the surfaces which it is used to join; and in general cements are comparatively brittle. At first sight one would suppose that the more cement there is used, the stronger will be the joint, and this is an error into which most inexperienced persons fall. Two pieces of earthenware, joined together by a layer of shellac as thin as possible, will adhere together and will be as strong at the junction as at any other part, while the same pieces united by means of a layer of the same cement an eighth of an inch thick, would fall apart on receiving the slightest jar. The rule which directs us to use as little cement as possible admits of no exceptions, and as a general thing the only way to obtain thin layers of cements that are to be used in a fused state, is to heat thoroughly the pieces that are to be united, and press them forcibly together.

The last point to which we shall call attention is the necessity for cleanliness, both in the preparation of the cements and in the application of them. It may be safely laid down as a positive rule that every extraneous substance that is mixed with the material of a cement is an injury to it. Glue prepared in a greasy pot cannot be expected to make a strong joint, and the presence of dust and dirt tends to weaken *all* cements. So, too, in the application of cements. If we attempt to glue together two surfaces of wood that are covered with dirt, the substances that are to be united are not wood to wood, but dirt to dirt, and the joint, instead of possessing the strength of wood

united by means of good glue, will have simply the strength of dirt. Moreover, we must remember that the different cements do not adhere with equal force to substances of different kinds. Thus glue adheres powerfully to wood and paper, but not at all to metal or glass. Shellac, if properly applied, adheres readily to earthenware, glass and metal, but not to some other substances. If, then, we apply glue to a greasy surface it will not stick. Hence the necessity for great cleanliness. All surfaces should be kept as clean as possible, or if they should get accidentally soiled, they should be carefully cleaned. The mere rubbing of two wooden surfaces with a dirty hand will weaken the subsequent glue joint by at least ten per cent. When glass or earthenware are accidentally broken, and it is not convenient to mend them on the instant, they should be carefully wrapped up in separate pieces of paper and laid away where they will not be soiled, and where the edges will not be chipped. In the case of broken glass or earthenware, the joint will be greatly disfigured and considerably weakened if the edges are chipped and broken by careless handling, or by being needlessly and frequently fitted together. Keep the pieces from contact with each other and with foreign substances, until you are ready to join them, and the joint will then be not only strong, but almost invisible.

It may be well to remind those who have had little experience in mending broken articles that it is quite important that the color of the cement should accord with the color of the article to be mended. A white porcelain cup mended with black cement would show some very ugly lines. If, however, a white cement be used, the lines of fracture will be invisible.

—Mr. S. H. Scudder, librarian of the American Academy of Arts and Sciences, has prepared a catalogue of all scientific publications, whether issued at stated or irregular intervals. The work will be published, and will extend to 300 pp., large octavo.

Beauty and Strength.

IT is a notable truth, that the most elegant forms are in general the strongest. The line of grace and beauty is not only correct as an element of art, but as a model for the architect and the engineer. The massive stone structures of olden times, in which huge flat stones took the place of arches, were singularly inelegant and very weak, when compared with the light and graceful arches of modern times. And it is not only in regard to the extensive works of the engineer and architect that this principle applies; in the designs of the carpenter, the machinist, the blacksmith, the tinsmith, and a host of others, it will be found that gracefully curved lines confer an element of strength as well as of beauty. Vibrations, when transmitted along such lines, are never suddenly checked, and the material is never exposed to those sudden strains which always occur wherever right angles and square joints are found.

Crossing the Atlantic in a Twenty-foot Boat.

EVERY ONE of our readers has probably heard of the feat of Captain Crapo and his wife, who recently crossed the Atlantic in a boat whose tonnage is a little over a ton and a half. The enterprise was a bold one, especially for a woman, and as no well-illustrated account has yet been published of the boat and her voyage, we feel sure that a large number of our subscribers, especially those interested in boat-building, yachting, canoeing, etc., will be interested in the following description.

No great problems have been solved, and perhaps nothing has been done, the possibility of accomplishing which with certainty could not have been predicted beforehand. Captain Crapo and his wife have, however, the merit of proving, by actual experience, that long voyages can be made, in very rough weather, in comparatively small boats; and to the captain is due the credit of showing just the means required for this end. Moreover, the fact that such

a small craft could live in the roughest sea, throws a good deal of light upon the possible migrations of prehistoric peoples, whose vessels were undoubtedly small and imperfect, but whose skill in managing them was unquestionably very great.

Fig. 1.—THE LITTLE BOAT THAT CROSSED THE ATLANTIC.

The voyage was undertaken by Captain Crapo, more in a spirit of daring adventure than of scientific research, but the same may be said of all the balloon voyages which are made, with, perhaps, one or two exceptions. The project occupied his attention for some time before he put it into actual practice, and having been on many whaling voyages, he was able to obtain clear ideas of the conditions required, and to work out the plans necessary for complying with them.

The "New Bedford," which is named after the city from which she sailed, resembles in model an ordinary whale-boat, but has rather more dead rise. She was built by Mitchel, of New Bedford, and is constructed of cedar on an oak frame, planked

both inside and outside, so as to ensure great strength.

The following are the principal dimensions: Length of keel, 13 feet; length over all, 19 feet 7 inches; beam, 6 feet; depth of hold, 2 feet 10 inches; draft (mean), 1 foot 1 inch; shear, 1 foot 4 inches; rise of deck beams, 4 inches; tonnage, C. M., 1.62.

The boat is schooner rigged; length of main-mast, 20 feet, 4 inches; length of fore-mast, 21 feet; length of boom, 10 feet; area of sails (fore and main), 25 square yards. She carried the American ensign and her own burgee.

The deck extends the whole length, with only two openings, each 24 by 18 inches, one forward (kept closed during the entire voyage), and the other aft, the latter being provided with a sliding cover. The centre-board was about 4 feet long.

Our engraving, Fig. 1, gives a very good idea of the general appearance of the vessel; Fig. 2 is a plan of the deck; Fig. 3 is a longitudinal section of the boat, and Fig. 4 is a cross section. The binnacle, with compass and lamp, are shown at *a*, Fig. 3; the water kegs, *c c c c c*, holding 20 gallons each, were disposed as shown in Figs. 2 and 4, and the sleeping berth of Mrs. Crapo at *b*, Fig. 2. This was so small that when she lay down her feet rested on the water kegs, and it was utterly impossible to turn round without first getting out. As for the captain, when he lay down, he was obliged to curl himself up, and the only times that he was enabled to fairly stretch his limbs was when he boarded passing vessels.

The equipment consisted of an anchor and cable, a drogue,* fifty fathoms of drogue line, a compass, binnacle and lamp, kerosene oil stove and utensils, five water kegs, etc. The stores consisted of 90 lbs. of biscuit, 75 lbs. of tinned meats, 100 gallons of water, together with a proportionate quantity of tea, coffee, sugar, and light articles generally.

The voyage took a much longer time than was expected, however, and the supply of provisions was found to be short. When four or five weeks out at sea, the water became unfit to use, and a fresh supply had to be obtained from passing vessels. A supply of water, provisions, and two bottles of brandy, were also kindly given by the captain of the steamship "Denmark," on July 8th. Some provisions and two bottles of wine were also obtained from the "Gustave d'Oscar," a Bremen bark, bound for New York.

During the voyage the sea broke over the deck only once. When a wave would approach, and there seemed to be every indication of its breaking over the boat, she would ride over it without even breaking the crest. An examination of the deck plan, Fig. 2, will show that the water kegs were stowed amidships, while the locker containing the stores was in the extreme stern; the living weight was also always very far aft, so that the centre of gravity of the whole was abaft the centre of length of the boat, thus presenting the long arm of the lever to advancing waves, besides bringing the centres of lateral resistance, load water line, gravity and buoyancy all at or near one plane; and this will account for the great seaworthiness of the boat.

When it was too stormy to sail, the drogue was thrown overboard, with fifty fathoms of line, and then the hatch cover was nearly closed, a small opening being left for ventilation. The vessel would ride to the drogue, while the captain and his mate would take a few hours' rest. Although the voyage was somewhat uneventful, the weather was rough and tempestuous, indeed, extraordinarily so for the time of the year. The captain thinks that if he had pursued a more northerly course, he would not have encountered such rough weather. No serious accident occurred, except the

*As some of our readers may not understand what a *drogue* is, and as the word is not found either in Webster or Worcester, we may say that it is a frame, usually of iron, to make it sink, covered with canvas, and so fastened to a line that, when drawn through the water, it must move flatwise, so as to offer a great resistance. It serves to steady a small vessel, and prevents it from drifting before the wind. The word is sometimes spelt *drug*, and is undoubtedly a mere corruption of *drag*.

loss of the rudder, which was twisted off, but the captain was of course provided with a second one. The voyage was, however, far from pleasant; no reading or amusement of any kind. The only excitement that was experienced was when, upon two or three occasions, they found themselves surrounded by a shoal of whales, that spouted and blustered a good deal. Mrs. Crapo was specially afraid of the whales. When favorable winds prevailed, the helm could not be left for a moment.

The experience of Captain Crapo tends to show that a life-boat should be provided with a large surplus of buoyancy forward, and that all her various centres should be massed aft of the centre of length. The well-known yacht "America," now owned by Gen. B. F. Butler, had all her centres massed at three-fifths of her total length from the bow, and her behavior at sea is very much the same as that of the "New Bedford," particularly in the feature of rising over a wave, instead of cutting through it, though not in nearly so marked a degree. But then the "America" is very sharp forward, and her greatest breadth of beam is at the same point as all her other centres, while the "New Bedford" is quite blunt forward, and her greatest beam is forward of the centre of her length, about the same distance that all her other centres are aft.

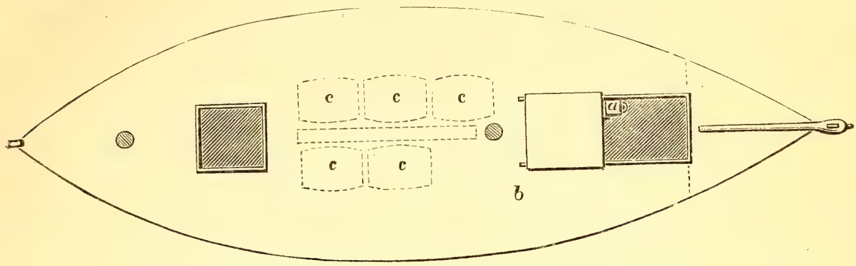


Fig. 2.—PLAN OF DECK.

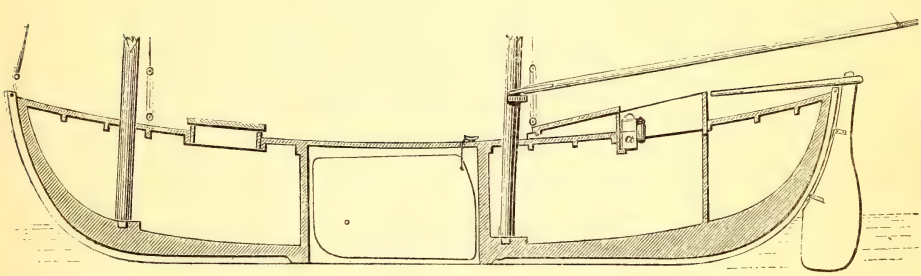

Fig. 3.—LONGITUDINAL SECTION.

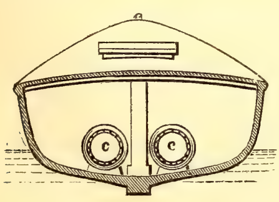

Fig. 4.—CROSS SECTION.

The "New Bedford" sailed from the town after which she was named on the 28th day of May, 1877, at half an hour after noon. The real start for the voyage across the Atlantic was, however, made from Chatham, Mass., at two o'clock on the afternoon of June 2d. She reached Penzance, Cornwall, Eng., on Sunday, July 22d, after a passage of fifty days from shore to shore.

Simple Lessons in the Art of Photography.

THE art of photography is one capable of affording a great deal of interest and pleasure, and some departments, and these, perhaps, the most pleasing, are so readily learned that we feel confident that if our readers only understood how simple it is, many of them would adopt it as a recreation. By it our summer wanderings and excursions may be enlivened, and the pleasant memories surrounding them may be perpetuated by views of the places and objects which we have visited. Truthful views of such objects as apparatus, machines, specimens of natural history, and various other objects may be taken either for transmission to distant friends, or for future reference and study. And with the advances which have of late years been made in the manufacture of simple forms of apparatus and fine qualities of material, the outfit required for commencing the practice of the art is not by any means expensive. We hope, therefore, to see ere long a large number of amateur photographic clubs organized all over the country. These clubs, by mutual intercourse between the members, will smooth the path of learners and greatly increase the interest and profit of the occupation by promoting exchanges. And we would remind such clubs that our exchange column is always open to them free of charge.

These photographic clubs are not by any means a novel suggestion. In England and Scotland they flourished extensively twenty years ago, and, we believe, many of them are still existing in a prosperous condition. In order to give those of our readers who have a taste in that direction an opportunity to make a commencement, we propose to explain in simple terms the principles of the art, and the rules for putting them in practice.

The art of photography depends for its success upon the changes which light produces in certain chemical compounds—particularly the salts or combinations of silver. These photographic effects of light are, however, produced with great power by but one of the three beams into which a ray of white light may be separated by a prism. These three beams give rise to the colors known as yellow, red and blue, and it is the blue ray that possesses in the highest degree what is called the actinic, or chemical power. The red ray is not nearly so efficient, and the yellow ray has scarcely any chemical power at all. Consequently, a room may be almost dark, from being feebly illuminated with powerful blue rays, and yet be very powerfully lit up, photographically speaking; while another may be quite well lighted, so far as mere vision is concerned, and yet be photographically dark, from the fact that the rays of light are all yellow, the blue rays having been excluded. These facts are very important, as we shall see when we come to give directions for arranging the work room, or *dark room*, as it is generally called.

Of the numberless processes for producing pictures, we propose to describe only one particular method, the collodion process, which is not only easily understood, but which also produces, with a comparatively small amount of study and experimentation, the finest results.

Pictures by the collodion process are taken either on glass or ferro-plates. They are called positives or negatives, according to the degree of exposure and development to which they have been subjected. Good ferrotypes or pictures taken on ferro-plates, are always good positives; but a good negative would make a poor positive. In a positive the collodion film is thin, and the silver deposit rather transparent, so that reflected light will clearly show all minute details. A negative is a positive to a certain extent, but the deposit of silver on the parts acted on by light is considerably denser, and the details of the picture can only be detected by transmitted light.

Beginners in photography should commence by making positives, either glass positives or ferrotypes, since this process con-

sists only of a small number of successive operations, and the final results are instantly obtained; while to make negatives and print from negatives demands the full and complete mastery of making positives, and in case of failure offers the experimentalist too wide a range in which to search for the causes of his disappointment. The hand must be trained to certain manipulations and motions, the eye must learn to observe and judge, and the necessary discipline of the two organs is most conveniently acquired in the simple process of making positives.

The apparatus and materials necessary to make positives are: 1. Camera with its lens. 2. Plateholder. 3. Tripod. 4. Bath. 5. Dipper. 6. Several wide-mouthed bottles. 7. A large and a small funnel. 8. Set of scales with weights. 9. A black focusing cloth about 1 yard square. 10. Glass plates or ferro-plates. 11. One yard of canton flannel.

The chemicals necessary are: 1. Bromo-iodized collodion. 2. Pure nitrate of silver. 3. Iodide of potassium. 4. Protosulphate of iron. 5. Acetic acid. 6. Hyposulphite of soda. 7. Alcohol. 8. Filter paper. 9. Rotten stone. 10. Shellac varnish. 11. Bicarbonate of soda.

The preparatory operations which are required before the plate can be exposed, must be conducted in the dark room, in order to retain the sensitiveness of the iodized silver film. The term *dark room* is to a certain extent a misnomer, since the dark room is not at all a dark room. At the commencement of this article it was stated that the actinic force of light is found mainly in the blue rays, while the yellow rays possess hardly any chemical properties. It is therefore only necessary to exclude all blue and red rays of light, and work with the illuminating power of the yellow rays. If we have a dark room with several windows, all the windows, with the exception of one, should be blocked out or darkened with some opaque material, for instance, three or four layers of dark-brown paper or black oilcloth. The remaining window is covered with four folds of yellow calico. This yellow curtain need not cover the whole window, but only two or three panes, provided the others are darkened in the manner just described.

In place of this modified daylight, gas or lamp light can be used. In this case the chimney or globe is surrounded with a yellow paper screen. Another very practical way is to paint three-quarters of the circumference of the chimney a dark yellow, with an alcohol varnish, to which iodine has been added till the desired color is obtained. By the latter arrangement white or yellow light can be thrown at will on the plate under operation. Have the dark room neither too dark nor too highly illuminated. In the former case you will not be able to watch the progress of the different operations; in the latter case all your pictures will be covered with an impenetrable veil.

The dark-room should be provided, near the window or lamps, with a table or strong shelf, on which to place the necessary chemicals and materials.

A good supply of water is also indispensable. For washing smaller plates the washing bottle, Fig. 1, answers very well. It is constructed in the following manner: Take a wide-mouthed bottle, of a pint capacity, with a tightly-fitting cork. The

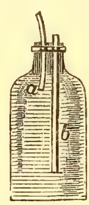

Fig. 1.

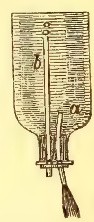

Fig. 2.

cork must be twice perforated to receive two glass or tin tubes, a short one, a, and a long one, b. As soon as the bottle is turned upside down, as seen in Fig. 2, tube b acts as a ventilator, freely admitting air, while out of tube a a continuous stream of water will flow.

For larger plates greater quantities of water are required. A very simple arrangement is to take a common waterpail, Fig. 3,

and drive into it, near the bottom, a wooden faucet, whose spout is covered with a piece of muslin or flannel to prevent impurities

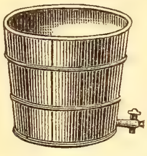

Fig. 3.

from passing upon the plate. Another vessel to receive slops, and a towel to dry the hands, will complete the furniture of the dark room.

To be continued.

Simple Legerdemain.

THE simple piece of apparatus, which is shown in the engraving illustrating this article will enable any one to perform

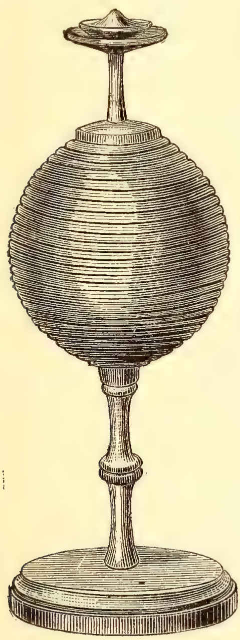

Fig. 1.

a little bit of legerdemain which will surprise almost any one that is not familiar with it. The construction of the apparatus itself constitutes a capital exercise for those who wish to become expert in the use of the turning lathe, and in succeeding numbers we will give minute directions for making it. Meantime we will give a description of its general construction and the method of using it.

Fig. 1 shows the apparatus as it appears when together. At first sight it would seem to be made out of a single piece, and as the entire surface of the oval part is finished off

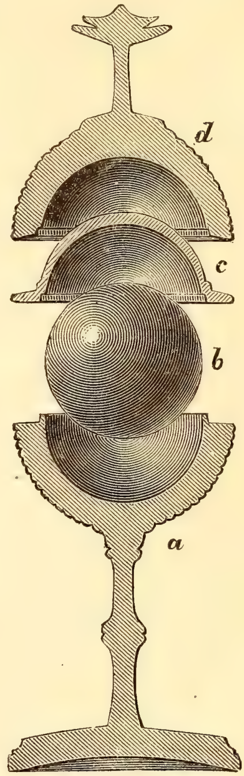

Fig. 2.

with a series of rings, the joints are invisible. In reality, however, it consists of four parts, as shown in Fig. 2: 1, the base and cup, *a;* 2, the ball, *b;* 3, the shell, *c;* 4, the cap or cover, *d.*

Suppose now that we wish to puzzle some of our friends. We must carefully conceal from them the existence of the shell, *c*, for it is upon this that the entire puzzle depends. The hollow part of this shell is an

exact imitation of the under or concave surface of the cap, *d*, and the upper or convex part is painted so as to exactly resemble the ball when it is sitting in the cup of the base, *a*. Let us therefore suppose that all four parts are together. We lift off the cap and the shell together, by taking hold of the edge of the latter. The ball is then seen in the cup. We remove it, replace the cap, and offer to pass the ball into the cup without taking off the cap. We then pretend either to drop it down from the top or to pass it up from beneath the table. The cap alone is now removed, leaving the shell in its place, and those present apparently see the ball in the cup. The cap is now replaced and an offer is then made to pick the ball out of a hat or pocket, or out of a lady's lap. The real ball is conveyed dexterously in the hand, and exhibited at the required place; the cap and shell are then removed together, as at first, and the cup is found empty!

Several variations may be made in the way of performing the trick, but under any circumstances it is very difficult for the uninitiated to detect it, and to those who see it for the first time, and who are not accustomed to such things, it looks like a veritable piece of *diablerie*.

It is not very difficult to make, but requires patience and delicacy of touch, and we know of nothing which will serve better to improve the amateur turner than the making of this little apparatus.

The Toad and its Habits.

Formerly the toad was considered a venomous reptile, but in our days its habits have been more carefully observed, and its great value to the pomologist and gardener has been fully established, on account of its propensity for destroying insects, especially those injurious to vegetation. We should, therefore, sedulously cultivate the friendship and crave the assistance of the insectiverous reptiles, including the snake, as well as that of birds.

Every tidy housewife detests the cockroach, mice, and other vermin. Two or three domesticated toads would keep the coast clear of these, and would be found more desirable than a cat, as they are wholly free from trespassing on the rights of man as does the cat. The toad is possessed of a timid and retiring nature, loving dark corners and shady places, but under kind treatment becoming quite tame.

Many instances might be cited of pet toads remaining several years in a family, and doing valuable service with no other compensation than immunity from persecution. All that is necessary to secure their co-operation, indoor or out, is to provide them with cool and safe retreats by day, convenient access to water, and they will go forth to the performance of their nocturnal duties "without money and without price."

In Europe toads are carried to the cities to market, and are purchased by the horticulturist, who by their aid are enabled to keep in check the multiplication of the insect tribes which prey upon their fruits, etc.

No one can study the anatomy of this reptile without being convinced of its perfect adaption to the sphere which it fills in the economy of nature. Its tongue, which is capable of great elongation, is attached to the anterior portion of the lower jaw; its free end, when the toad is in repose, reaching down to the borders of the stomach. The moment the toad sees its prey, its eyes sparkle, its toes twitch, and quicker than the eye can follow, the insect is transfixed and conveyed to the stomach of the captor.

— A writer in the *English Mechanic* says that the oil which he has found to remain longest fluid and free from acid, is neat's-foot oil, which has been carefully purified by hanging strips of lead in it, and exposing it to a strong light. Several weeks exposure to direct sunlight are required to accomplish this. Olive and other vegetable oils contain too much vegetable albumen to be suitable.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ADVERTISEMENTS—30 cents per line.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Concerning Ourselves.

A FEW days ago there fell into our hands a copy of a journal which professed to occupy ground somewhat similar to our own. It consisted of eight pages, one of which was advertising, one was devoted to a story, two to practical matters, and four were wholly occupied with puffs of the editor, the publisher, and the journal itself! We do not propose to follow this example. At the same time, however, a few words may not be inadmissible.

We are happy to be able to say that the reception accorded to our first number has been such as to assure us that the YOUNG SCIENTIST meets a well defined want, and that it will receive such support as will enable us to improve it constantly, both in matter and illustrations. As evidence of this, our readers will notice that the present number has been increased by four pages of reading matter.

That the YOUNG SCIENTIST is not yet anything like what we hope to make it, we freely confess. It must be remembered, however, that in order to *make* a good journal we must *have* a good journal, for it is only a good journal that can attract to itself the necessary material. Old contributors have to be trained to our special methods and wants, for we have already had abundant evidence that although men may write successfully for other journals, they cannot, without special effort, produce articles which we regard as suited to our columns. New contributors must be taught by the example of articles already published, and this presupposes an established journal.

Our object is to make this journal a practical guide to the young scientist, in the laboratory and the workshop. We hope to interest him by new experiments, new tools, and new apparatus, or at least by new and simple directions for making and using old ones, and we hope to cover such a wide range that, from the boy who has only a jack-knife for whittling, to the professor who desires to study the construction of his apparatus, all will get their fifty cents worth out of our pages during the course of the year.

A Good Watch for a Dollar.

WE have so much faith in the skill and intelligence of our American mechanics that we believe that if any one were to ask for bids for a contract for five million watches, capable of keeping time to within two minutes per week, and enclosed in neat nickel cases, with a stem-winding arrangement, he would have his order filled at a price which would enable him to sell the watches for one dollar each. At present, however, there are no such watches in market, and yet we see constantly advertised, "Good time-keepers, with steel works, for one dollar." What are they?

They are twenty-five cent pocket compasses, with a small brass gnomon for a sun dial. The steel "works" consist of a simple steel magnetic needle, and the whole affair will indicate correct time, provided the sun is shining and the observer is very skilful. These "perfect time-keepers" are perfect frauds, and yet advertisements offering them for sale are to be found in many of our most respectable papers.

They are a fitting companion to the Lefevre Diamonds or Brilliants, against which we cautioned our readers in a previous issue. Next!

Will it Show the Animalcules in Water?

THE first question always asked when a beginner is about to buy a microscope is, "How much does it magnify?" The second as invariably is, "Will it show the animalcules in water?" Let us try to answer the latter question in such a way that the young microscopist may have a clear idea of what he ought to expect.

Pure water contains nothing that can be seen with any microscope ever made, up to the present time; no solid particles, no animalcules, no minute vegetables, no spores or germs. *Good* water, such as is ordinarily procured from wells, and such as has been obtained by carefully filtering rain or river water, contains nothing that is visible to any of the microscopes ordinarily used by our ablest scientific men. Over and over again people have brought their instruments to us with the complaint, "My microscope is out of order, for I have carefully examined a drop of water with it, and I can find nothing!" The microscope was all right, but the owner did not know what he ought to expect.

How, then, are we to account for those wonderful pictures of "a drop of water," which we find in almost every popular book on science? Are the animalcules which are shown in them mere creatures of the imagination, which have no real existence?

The creatures ordinarily pictured as "the inhabitants of a drop of water" are in almost all cases the inhabitants of stagnant pools, and to see very many of them requires no microscope at all. More than this, however, where a so-called *drop* is shown, the book-maker almost always manages to give what would be the full complement of inhabitants for some hundreds of drops, not with the intention of deceiving, but for the purpose of making his book or picture more interesting.

That these statements in regard to the popular pictures and descriptions of a drop of water are correct, is easily proved. We have before us at the present moment half a dozen books in which such pictures are found. Selecting one of the most popular and interesting—Miss Catlow's "Drops of Water"—we find four beautiful engravings, each showing an imaginary drop of water and its inhabitants. But these inhabitants can in general only be found after the most diligent search, and in special localities. We might search the water from a dozen ordinary wells before we succeeded in finding any of them. Many of them can only be found in clear, though stagnant pools, while others must be looked for in water which contains decaying animal and vegetable matter. And of all the objects shown in the four "Drops," there is not one that cannot be clearly seen with a microscope magnifying one hundred diameters. Even a good hand magnifier, such as those now commonly sold in hard rubber, and consisting of three lenses, will show their outlines and forms, so that they can be recognized. It is these objects which are usually known as "animalcules," and in general it is much larger creatures (water fleas and the larvæ of insects, for example) that are exhibited by sidewalk showmen under this name. A favorite subject with such exhibitors are the eels in paste or vinegar. Both these objects, as well as the water-fleas, and even the *Volvox Globator*, or beautiful "globe animalcule," as it is popularly called, may be seen by the naked eye, *if properly illuminated.*

We must remember that these minute forms of life differ as widely in size as do the larger animals with which we are more familiar. The whale and the minnow do not differ more in size than do some of the living creatures which are the subjects of study under the microscope, and the largest of which are barely visible to the naked eye. To see the very smallest animalcules, the very beginnings of life, if we may so speak, will severely tax the power of the very best microscopes. But, on the other hand, any good magnifier—such as may be had for a couple of dollars—will enable us to see hundreds of the most interesting animalcules in water.

Laboratory & Workshop

[Specially written for the YOUNG SCIENTIST.]

The Art of Sharpening Edge Tools.

By JOSHUA ROSE, M. E.

NO. II.

Our next example shall be the sharpening of a pair of scissors, which is a fair representative of a class of severing tools which operate by a concentration of pressure upon a narrow section of the material to be separated, rather than by the acuteness of the edges. Suppose, for example, that we open a pair of scissors, and, placing a sheet of paper upon a table, or upon a piece of board, attempt to cut it with one edge of the scissors used as a penknife blade. We shall find that, with both considerable pressure and motion, it will be difficult to cut the paper, even though the scissor edge is in excellent order. This teaches us that the action is not purely one of cutting on the wedge principle, and leads us to a consideration of the difference between cutting and shearing.

Cutting instruments act by reason of the fineness of the edge which enters the material, and which, acting as a wedge, divides the substance operated upon; they are therefore dependant upon the fineness of the entering end of the wedge (as the cutting edge may be properly termed) in a far greater degree than is the case with shearing tools. Hence, in the former, strength is much less important than in the latter. The reason for this we may very readily perceive by a little investigation. Suppose, for example, that we take a piece of wood and cut it slowly with a knife; we shall find that in the beginning of the operation the edge enters the wood very easily, but that the resistance increases as the knife blade enters. This is because we have at first to sever the fibres of the wood only, while afterwards we have to continue that severing process, and also to force the already severed portions asunder to allow the thicker parts of the wedge or knife blade to pass. We have thus, to a certain extent, the strength, as well as the resistance to severance of the material, to encounter. If we rest the back of the knife blade upon a support, such as a table, place the piece of wood upon the edge of the knife blade, and then press another knife edge upon the top of the wood, with the two knife edges exactly facing each other, each edge will enter easily at first, because the separation of the fibres is the only resistance offered; but as the knife blades enter, the friction between the sides of the severed wood and that of the blades will increase until it absorbs the greater part of the power applied, teaching us that for shearing duty the angles of the side facets forming the cutting edge should stand at a right angle to the surface of the work, so that the latter shall not rub against them after severance. This then determines that the side facets of each leg of the scissors shall stand at least parallel with the line of motion of the legs when in use. In actual practice we shall find that these side facets have a little clearance, being ground away as the cutting edge is receded from in the width of the leg, so that when the edges, at any point, are in contact, the side facets form an obtuse angle one to the other. In addition to this, there is given to these faces a slight twist in their planes, and a curve in their lengths, whose usefulness will be hereafter explained.

We may now consider the angle necessary to what may be called the top facet of the cutting edges—that is to say the narrow surface (at the cutting edge) which stands at about a right angle to the line of motion of the scissor legs when in use, and this is of the utmost importance. In a pair of scissors, the material to be cut is generally weak and pliable; hence it will give way whatever be the angles of the faces, so that all we have to do is to consult the best angles to produce the required cutting edge. The action being that of a wedge, it would appear that the more acute they are the more easily they would cut; this, however, is not the case, for the following reasons.

It is obvious that the substance is severed at the point of contact of the scissor edges, and that if those edges become rounded the pliable material will be apt to spring the legs apart and slip between them; hence we have to consider the angle that will best enable the edge to resist becoming rounded, while at the same time give an edge sufficiently acute to cut. Let it be remembered that the distance of the ends or points of a pair of scissors from the joint which holds them together, enables very little pressure at the points to spring them apart; hence as the edge becomes dull, or the end becomes rounded, the points *do* spring apart, the substance or work passing between their side

faces. Now, the more acute the angles of the faces forming the wedge, the easier its edge will break off, abrade away, or bend over. Hence it is found best to make the top facet stand at an acute angle of about 4° or 5°, or, in other words, at very nearly a right angle to the side face of the leg.

We have now to consider a very important point in scissor grinding and sharpening. The distance of the scissor points from the joint which holds the legs together, renders very little pressure at the points sufficient to spring them apart, and slide past the work; hence the scissors may be tight enough at the joint to cut well near the joint, and yet not cut at the points, although the edge may be equally sharp from end to end of the edge. To obviate this difficulty, and to cause the cutting edges to fairly meet, the side faces of each leg are curved in their lengths, so that when the legs are open and we look at them edgewise, they appear to cross each other; as a result the more we close them the more the edge of one is pressed to that of the other, and this compensates for the increased distance from the joint. Now if the joint of the scissors becomes loose, a pressure of the fingers must be relied upon to keep the edges in contact as the legs close. From these considerations we may perceive that, if, to sharpen a pair of scissors, we grind them on the side faces, we destroy or remove the bend in the length of the legs; hence the top or narrow faces *only* should be ground, unless, indeed, the legs are taken apart, and then we may grind the side faces, but even in that case it is not desirable to do so, because the proper amount of curve and twist upon those faces requires a good deal of experience to determine, and we are not likely to improve upon the practice and experience of the original manufacturer, who has made the matter a special study. Furthermore a very little error in grinding the surface of the joint will have considerable effect at the points, making them come together with too much or too little side pressure; hence it is always safer and better to grind the narrow faces only. A loose screw or rivet is a great defect in scissors, but if the joint is to be tightened by rivetting, the legs should be opened wide while using the hammer, otherwise the edges will be damaged at their point of contact. If the joint is a close fit, scissors may be sharpened to some extent by simply rubbing the narrow face or facet with a narrow surface of steel as the back of a knife blade, which will throw over a coarse wire edge.

Some of my young friends may say, "Does it require so many words to tell how to sharpen a pair of scissors?" To such I answer, yes it does, if the learner is to have such a knowledge of the subject as to make him *feel* that he knows *how*, and not be liable to adopt some wrong plan, which somebody else may say will answer. There are right and wrong ways to do everything, and the only way to eliminate the wrong ways is to show the principles governing the right ones. Then we shall know *why* as well as *how* the results are obtained, the *why* being almost or quite as important as the *how*.

Mechanical Genius.

I know at least a score of men who, though intelligent enough in other respects, do not know how to drive a nail in a workmanlike manner. As boys, they were educated with a view to practicing certain vocations or professions, and mechanical arts were completely ignored by their unwise parents or guardians. Now, it is essential to every man—lawyer, preacher, physician, merchant—to know some of the principles of mechanical art, and how to apply them, for no one leads an industrious life without frequently seeing the use of such knowledge. There are certain mechanical rules that apply to almost every piece of work that man attempts to perform, from the folding of a paper to the matching together of two boards, and the bungling manner in which these things are generally done, shows how little idea men have of mechanism. Then, fathers, whether city men or country men, fit up a workshop for your boys. A small set of tools of the best material will not cost much—not more than ten or twelve dollars at most—and they will soon return you thrice their value in good accomplished. Where there is a comfortable workshop, supplied with good tools, the boys are seldom known to leave it upon leisure days to loaf in the streets. If nothing else is given them to do, they will be manufacturing wind-mills, sleds, weather-cocks, hand-carts, etc., and every hour thus employed adds to their skill as workmen. Very soon they will be able to make rainy days as profitable as

others, repairing or making very many important fixtures about the house. We know boy mechanics who have furnished their homes with brackets, flower-stands, step-ladders, and a hundred and one other things convenient and valuable.—*Exchange.*

Cheap Stage Forceps.

The stage forceps is one of the oldest accessories of the microscope, and unless we are provided with other and better appliances, it is one of the most valuable. In examining small opaque unmounted objects, such as leaves, insects, minerals, shells, etc., it is often impossible to get along without it.

A few days ago a young friend, who had derived great pleasure from a five dollar microscope, felt the want of a stage forceps, and set out to buy one. He found none for a less price than $2.25, and the most of them he could not use at all with his instrument without having it specially fitted. To pay $2.25 for an accessory for a $5.00 microscope seemed rather disproportionate. In this dilemma we set to work to make a substitute, and succeeded so well that our ten-cent stage forceps proved quite as efficient, and a great deal more convenient than those usually sold in the shops.

The engraving, of which Fig. 1 is a perspective view, and Fig. 2 a section, explains its construction. We took a wooden slide, and through the centre we bored a hole three-quarters of an inch in diameter. At one end we bored another hole to allow a small screw to pass through easily, and countersunk the lower side of the hole so that the head of the screw might not project beyond the wood. This screw fastened the cork, C, so that it might turn steadily, like a post, and yet have no shake. Through the cork we passed a darning needle, on the end of which was stuck a small cork. The cork was prevented from either turning round or coming off by means of a common pin thrust through it, and through the eye of the darning needle. The whole thing can be made by any boy or girl.

To use it we dipped the point of the darning needle in Canada balsam or mucilage, and touched it to the article to be examined. The small objects usually examined are held quite firmly by this simple contrivance, and may be exposed to the light in any direction by turning the needle round by means of the cork handle.

The cork handle itself is of great use in the examination of cabinet specimens of insects. They may be taken out of their cabinets, and the pins by which they are held may be stuck in the cork, after which they may be turned round in any way and examined. To remove them from their own pins spoils them, and if the pins are simply stuck in a wooden slide, the insects cannot be examined on all sides.

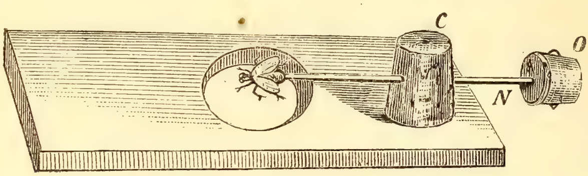

Fig. 1.

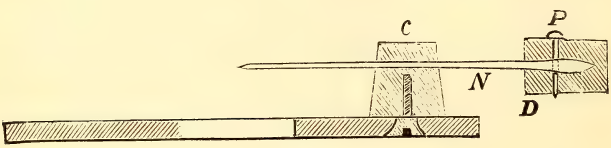

Fig. 2.

The screw, S, being fitted loosely to the slide, and firmly to the cork, C, the latter can turn freely, as on a pivot. If the screw should get loose in the cork, it may be heated and cemented in firmly with a little sealing-wax. The wooden slide is placed under the clips of the stage, and moves about like a common glass slide. This is on the plan of the forceps-carrier, described at page 94 of "Practical Hints on the Selection and Use of the Microscope."

The large hole allows light to pass from the mirror for the illumination of transparent objects. In examining opaque objects, it is well to place a black card beneath them.

How to Measure the Magnifying Power of Microscopes and Telescopes.

There is probably no class of observations in which the senses are so likely to be deceived as in estimating the magnifying power of microscopes and telescopes. It is not uncommon to find lenses of moderate powers condemned on the one hand as greatly less powerful than they really are, and on the other hand extolled as something wonderful. Thus we see in our streets cheap microscopes of very moderate power advertised as the most extraordinary instruments, because they show the eels in paste, while just as often it happens that really good microscopes, of much higher power, are condemned as weak, because, having been applied to the examination of objects with which the observer is familiar, they do not reveal any very extraordinary features.

The real facts in these two cases are that the eels in paste, provided they are well illuminated, are quite visible to eyes of ordinary keenness of vision, while ordinary objects, if carefully studied under low powers, reveal many features which are not to be seen at a casual glance, or even by the most careful study by the naked eye.

The fact that when our senses are not guided by accurate means for measurement they are very unreliable guides, will, nine times out of ten, be shown by the following experiment: Take a common opera or spy-glass, magnifying five to fifteen times, and allow some of your friends, who are unaccustomed to astronomical observations, to look through it at the full moon. In all probability they will declare that the glass does not magnify at all, but that, in fact, while the moon appears a little brighter and clearer, it seems rather smaller than otherwise! After having made this examination thoroughly with one eye, the other having been kept closed, let the person who has been observing now look at the moon through the telescope with one eye, while the other is kept open and also directed to the moon. The obvious difference in size will be perfectly astonishing. The moon seen through the telescope will now appear magnified to its full extent, and the fallacy of the first observation will be apparent.

This simple experiment, in which the observation is made by what is known as *double vision*, one eye being aided by the instrument, and the other eye observing the object without any such aid, is the first step towards an accurate measurement of the magnifying power of any glass. For if we could count exactly the number of times that the magnified image is larger than that which is unmagnified, it is evident that we would have an exact expression of the magnifying power. To do this with the moon is not very easy, unless we have instruments which are specially adapted to the work. Let us therefore turn our telescope or opera glass to a brick wall, in which the individual courses are distinctly marked. The distance at which we should stand from it should be as great as possible, provided we can see and count the courses of bricks clearly. If we now look at the wall through the telescope with one eye, and directly with the other eye, we will find that each course of bricks, as seen through the telescope, covers several courses as seen without it, and it will be easy to bring the magnified image of one of the courses into such a position in relation to the unmagnified image that we can count exactly how many of the latter are covered by the former. Let us suppose that the number is five, or, in other words, that one brick seen through the opera glass covers exactly five as seen with the naked eye. In this case the magnifying power of the opera glass is obviously five diameters.

By this simple method it is easy to determine the magnifying power of common telescopes and opera glasses with sufficient accuracy for all ordinary purposes, but when we come to apply this system to microscopes, the conditions are so different that special appliances and methods are necessary. These we propose to consider in our next issue.

Characteristics of Various Woods.

An exchange gives some interesting items concerning the commercial value and properties of the better known woods:

Elasticity.—Ash, hickory, hazel, lancewood, chestnut (small), yew, snakewood.

Elasticity and toughness.—Oak, beach, elm, lignumvitæ, walnut, hornbeam,

Even grain (for carving or engraving.)—Pear, pine, box, lime tree.

Durability (in dry works).—Cedar, oak, poplar, yellow pine, chestnut.

Building (ship-building).—Cedar, pine (deal), fir, larch, elm, oak, locust, teak. Wet construction, as piles, foundations, flumes, etc.—Elm, alder, beech, oak, plane tree, white cedar. House building.—Pine, oak, whitewood, chestnut, ash, spruce, sycamore.

Machinery and millwork (frames).—Ash, beech, birch, pine, elm, oak. Rollers, etc.—Box, lignumvitæ, mahogany. Teeth of wheels.—Crab tree, hornbeam, locust. Foundry patterns.—Alder, pine, mahogany.

Furniture, common.—Beech, birch, cedar, cherry, pine, whitewood. Best furniture.—Amboyna, black ebony, mahogany, cherry, maple, walnut, oak, rosewood, satinwood, sandalwood, chestnut, cedar, tulip wood, zebra wood, ebony.

Of these varieties, those that enter chiefly into commerce in this country are, oak, hickory, ash, elm, cedar, black walnut, maple, cherry, butternut, etc.

BOOK NOTICES.

The Art of House-Painting: Being a Clear and Comprehensive Record of the Observations and Experiences, During Many Years, of a Practical Worker in the Art, and Designed to Instruct and Assist in the Every-day Work of Painters and Others. By John Stevens. Price 75 cents. New York: John Wiley & Sons.

This work is eminently practical, the directions being plain and easily followed. It is intended quite as much for farmers, householders and others as for professional painters. It touches upon almost every point that is likely to occur in every-day practice, from the selection and care of the brushes and material to the application of the paint, and must prove very generally useful.

St. Nicholas. It is no exaggeration to say that this is the handsomest and brightest paper for young folks now published in the English language. We never yet saw a family of children to which a copy of "St. Nicholas" did not carry unmixed delight. Twelve such seasons of pleasure can be had for $3.00, and the publishers have taken a sensible and effective way of doing good by offering to give, for three new subscribers, a copy to any poor, sick or crippled child, whose name may be sent at the time of sending in the subscriptions. Those of our young friends who have kind, warm hearts, can find no better way of conferring happiness. Address Scribner & Co., 743 Broadway, New York.

Popular Science Monthly. The March number of this valuable journal is at hand, and is filled with interesting and important matter. The "Popular Science Monthly" is not in any sense a technical journal; it rigidly excludes those articles which are suited only to the wants of the professional specialist. But as an exponent of scientific progress, it is undoubtedly the best (we had almost said the only) journal for the people at large. Those who do not make science the business of their lives, but who yet desire to keep *au courant* with the scientific thought and work of the day, cannot afford to be without the "Popular Science Monthly."

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge.* Buying and selling must, of course, be carried on in the advertising columns.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a good aquarium, medium size. State what is wanted in exchange. R. H., 8 Beekman Place, New York.

Publisher's Department.

Sign Your Name Plainly.—Very few persons can write a signature so that it can be read. We involuntarily get into the habit of writing our names rapidly, and the result is that our correspondents cannot read them. Attempts have been made to obviate this difficulty by means of stamps, but hitherto stamps, if good for anything, have been clumsy, bulky, and the very reverse of portable. The latest thing of this kind, however, is a pocket stamp, which can be attached to a pencil. It is neatly mounted in a nickel-plated case, and protected by a cover, and the rubber stamp gives a clear, sharp impression, which can never be misinterpreted. Another advantage is that they are very cheap. Address Scott & Co., 291 Broadway, New York.

A Substitute for Mucilage.—Messrs. Shipman & Sons, of 10 Murray street, New York, have just put on the market a very excellent substitute for mucilage. It is a thick pasty mass, of wonderfully adhesive power, much more convenient to use than mucilage, and not liable to turn sour and offensive like paste. For the editor's desk it is just the thing, and it is excellent for scrap books and similar work, as it does not render the scraps transparent.

The Young Scientist

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

Vol. I. NEW YORK, MARCH, 1878. No. 3.

How to Read a Drawing.

ALMOST every reader of this journal will, at some time or other, have occasion to construct some machine or piece of apparatus from drawings, and it will at least be necessary for him to know how to read a drawing, even if he should not be able to make one. We propose to give just such information as will enable our readers to make practical use of any working drawing that may be placed before them.

Drawings are of several kinds, such as perspective, isometric, orthographic, etc. It will suffice here if we call attention to the difference between perspective and working drawings. Perspective drawings are similar to the engravings usually given in books. Thus, the boat, on page 15 of the previous issue of this journal is in perspective. As a very simple example of such a drawing, and of its advantages and defects, let us take two blocks of wood placed one on the other, as shown in Fig. 1. The precise arrangement of the two blocks, and the

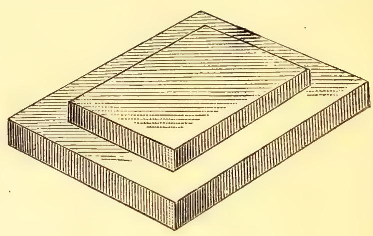

Fig. 1.

general appearance which they present are very well shown, but it would be impossible for one not thoroughly versed in drawing to ascertain the exact size or proportion of the different parts. Measured by the dividers, the further ends of the blocks are narrower than those that are nearer, and unless the reader is able to lay out the lines according to which the drawing was made, it will be

impossible for him to say whether this difference is due to actual size, or to the convergence caused by the perspective. And if instead of a simple pair of blocks, like those shown, the arrangement were a complicated machine, it would require a very expert draughtsman indeed to determine the real sizes of the different parts. This feature, which is very obvious when once pointed out, renders drawings made in perspective almost useless in the workshop.

Working drawings are therefore made according to the simplest possible system, the outlines being drawn as if the object were viewed from an infinite distance. A few illustrations will explain this better than a volume of words. In Fig. 2 the two

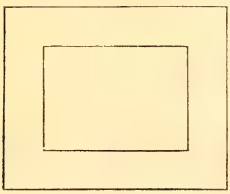

Fig. 2.

blocks are shown resting on each other, the observer being supposed to be situated at a great height above them. As seen in Fig. 2, however, it would be impossible to say whether the lines bounding the inner figure denote a hole or a projection. To avoid any such ambiguity, draughtsmen are in the habit of introducing what are called *shade lines*—that is to say, thick lines, such as are shown in Figs. 3 and 4. In Fig. 3 the outlines are shaded as if the inner rectangle represented a hole; in Fig. 4 the shading

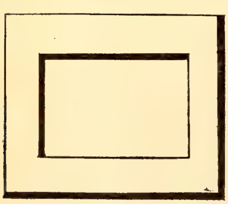

Fig. 3.

represents a projection, and the impressions made on the mind by such lining is fortunately quite definite. No one could mistake Fig. 3 for two blocks lying one on top of the other, or Fig. 4 for a block with a hole in it. Nevertheless such shading is to a

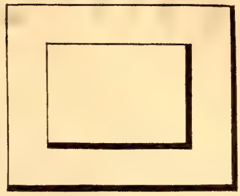

Fig. 4.

certain extent conventional, that is to say it is followed by a sort of agreement amongst draughtsmen without regard to actual light and shade, as existing in nature, for in mechanical drawing the light is always supposed to fall in one direction, which is such that the edges bounding the right hand and lower surfaces on the drawing are shade lines.

But although the reader would have no difficulty in determining that Fig. 3 is a block with a hole, and Fig. 4 a block with a projection, these figures give no idea of the depth of the hole or the height of the projection. To determine these points in this kind of drawing, other figures must be introduced. These figures are known as *elevations* and *sections*, and will occupy our attention next month.

A Good Education.

THE late Edward Everett condensed into a single brief paragraph his estimation of what constituted a good education. Here it is: "To read the English language well, to write with dispatch a neat, legible hand, and be master of the first four rules of arithmetic, so as to dispose at once, with accuracy, of every question of figures which comes up in practice. I call this a good education. And if you add the ability to write pure, grammatical English, I regard it as an excellent education. These are the tools. You can do much with them, but you are hopeless without them. They are the foundation; and unless you begin with these, not with flashy attainments, a little geology, and all other ologies and osophies, are ostentatious rubbish."

[Specially written for the YOUNG SCIENTIST.]

Wood Turning Tools.

BY JOSHUA ROSE, M. E.

THE beginner usually finds a great deal of difficulty in the use of hand tools for turning wood, the reason being that if the tool is held in a wrong position with relation to the work, it is apt to run into the material, and is sometimes even forced from the hand of the operator. If the principles governing the use of such tools be once properly understood, the merest tyro may handle them with confidence, and wood turning becomes an instructive and pleasant amusement.

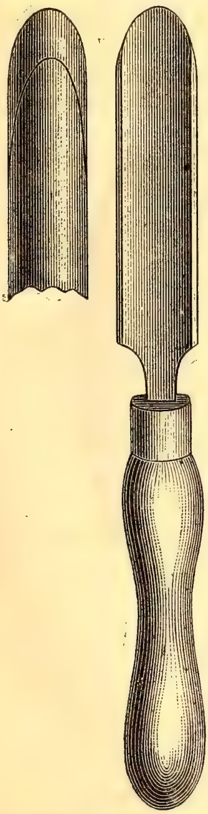

Fig. 1.

The principal tool is the gouge, shown in Fig. 1. It is used mainly to rough the work down to the shape, and nearly to the size that is wanted, leaving a little for other tools to finish, but in the hands of real experts, work may be finished very well with the gouge, rounding over corners or curves, and hollowing out sweeps with a clean and smooth finish.

The proper way to hold a gouge is shown in Fig. 2, in which the cut taken by the tool is being carried from right to left, the

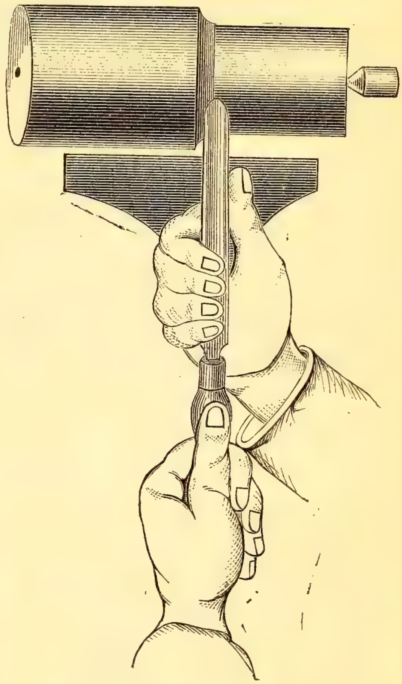

Fig. 2.

face plate of the lathe being on the left side so that by holding it in the manner shown the body and arms are as much as possible out of the way of the face plate, which is a great consideration in short work. But if the cut is to be carried from left to right, the relative position of the hands may be changed.

When the work runs very much out of true, or has corners upon it, as in the case of square wood, the fore finger may be placed under the hand-rest, and the thumb laid in the trough of the gouge, pressing the latter firmly against the lathe rest, in order to steady it. This is necessary to

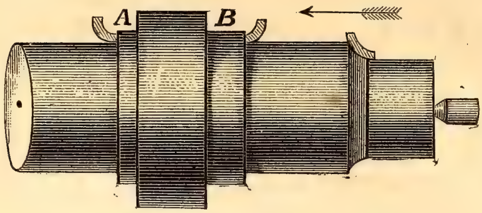

Fig. 3.

prevent the tool edge from entering the work too far, or, in other words, to regulate the depth of the cut, and prevent its becoming so great as to force the tool from the hands or break it, as is sometimes the case under such circumstances. When the gouge is thus held, its point of rest upon the lathe rest may be used as a fulcrum, the tool handle being moved laterally to feed it to the cut, which is a very easy and safe plan for learners to adopt, until practice gives them confidence. The main point in the use of the gouge is the plane in which the trough shall lie. Suppose, for example, that in Fig. 3 is shown a piece of work with three separate gouge cuts being taken along it, that on the right being carried in the direction of the arrow. Now the gouge merely acts as a wedge, and the whole of the pressure placed by the cut on the trough side or face of the gouge is tending to force the gouge in the direction of the arrow, and therefore forward into its cut, and this it does, ripping along the work and often throwing it out of the lathe. To avoid this the gouge is canted, so that when cutting from right to left it lies as shown at B, in which case the pressure of the cut tends rather to force the gouge back from the cut rendering a slight pressure necessary to feed it forward. The gouge trough should lie nearly horizontal lengthwise, the cutting edge being slightly elevated. The gouge should be ground, as shown in Fig. 1, special reference being made to the back view, where it will be noticed that the curve is ground well down the sides of the convex back, which is necessary to make the sides of the cutting edge keen and sharp.

The gouge always requires to be oilstoned, the trough being stoned with a slip of stone lying flat along the trough, the back being rotated upon a piece of flat stone and held with the ground surface flat on the surface of the stone, and so pressed to it as to give most pressure at and near the cutting edge.

For finishing flat surfaces, the chisel is

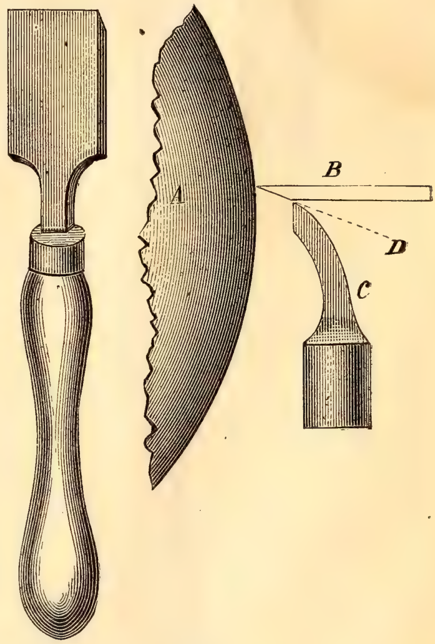

Fig. 4.

employed; it should be short, as shown in Fig. 4. It must be carefully ground, and oilstoned with the surfaces level with the stone, the surface nearest the edge being pressed the firmest to the stone. The posi-

tion in which it should be held is shown in the cut, Fig. 4, A being the work, B the chisel, and C the lathe rest. Some expert workmen hold it at an angle as denoted by the dotted line D, which makes it cut very freely and clean, but increases the liability to dig into the work; hence learners should hold it as shown.

Another excellent finishing tool is the skew-chisel, so called because its cutting edge is at an angle, or askew with the body

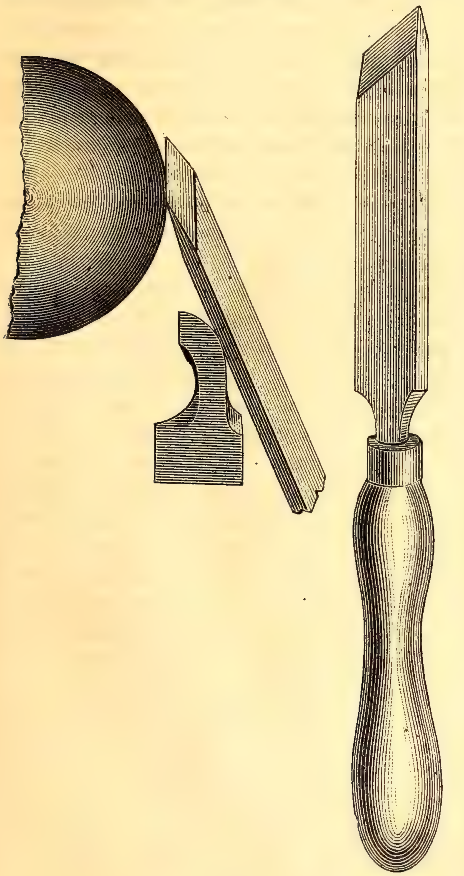

Fig. 5.

of the tool. This tool will cut very clean, leaving a polish on the work. It also has the advantage that the body of the tool may be kept out of the way of flanges or radial faces when turning cylindrical work, or may, by turning it on edge, be used to finish radial faces. It is shown in Fig. 5 by itself, and on the left turning up a globe. It is held so that the middle of the edge does the cutting, and this tends to keep it from digging into the work. The bevels forming the cutting edge require to be very smoothly oilstoned.

The whole secret of the skilful and successful use of this valuable tool lies in giving it the proper inclination to the work. It is shown in Fig. 6 at E, in the proper position for taking a cut from right to left, and at F in position for taking a cut from

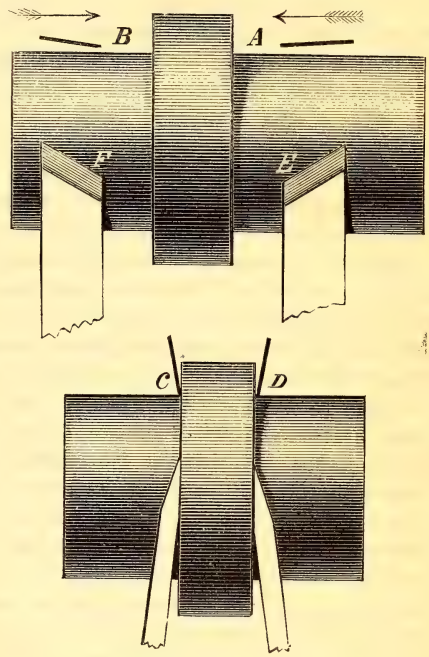

Fig. 6.

left to right. The face of the tool lying on the work, must be tilted over, for E as denoted by A, and for F as denoted by the line B, the tilt being only sufficient to permit the edge to cut. If tilted too much it will dig into the work; if not tilted the edge will not meet the work, and therefore cannot cut. For cutting down the ends of the work, or down a side face, it must be tilted very slightly, as denoted by C D, the amount of the tilt regulating the depth of

the cut, so that when the cutting edge of the tool has entered the wood to the requisite depth, the flat face of the tool will prevent the edge from entering any deeper. In cutting down a radial face the acute corner of the tool leads the cut, whereas in plain cylindrical work the obtuse is better to lead.

For cutting down the ends, for getting into small square corners, and especially for small work, the skew chisel is more handy than the ordinary chisel, and leaves less work for the sandpaper to do. Beginners will do well to practice upon black walnut, or any wood that is not too soft, roughly preparing it with an axe to something near a round shape.

What is a Diatom?

MR. CHARLES STODDER answers this question in the *Science Observer:*

I take my instrument from its case, put on a 1-6 or a 1-10 objective, and on the stage an *Aulacodiscus Oregonus* or a *Coscinodiscus oculis iridis*, and tell them to look. Then follow the exclamations: how beautiful! how mathematically regular! what exquisite lacework! Then an effort to see the object on the slide without the microscope. I take the slide off, hold it to the light, and there is nothing visible. Then follows the question, What is it? I give, perhaps, the specific name, but that conveys no idea; then I say it is a diatom. But to most people that also is without meaning (the word not being in Worcester), and the question follows, What is a diatom? That question I propose to answer here very briefly and imperfectly, for a full reply would require volumes, some of the most costly works published being devoted to the diatoms, Ehrenberg's "Micro-Geology," Schmidt's "Atlas," (now being published), to be followed by Prof. Hamilton L. Smith's great work, the work of many years.

Botanists divide all vegetation into two great groups, flowering and flowerless. Diatoms are plants, belonging to the flowerless class, or algæ. They are unicellular, *i. e.*, the whole plant is one single cell; they are all microscopic, only a few of the thousands of named species are visible to the naked eye, and then only as mere specks, but the eye must be armed with the microscope to make out the detail of the structure of the largest, while for the study of the details of the smallest forms the very *highest quality* of instrument must be used, together with a magnifying power—which is an entirely different thing from quality—that was scarcely attempted twenty-five years ago. Probably no scientific study has so much promoted the great improvement in microscopic lenses that has been made in England and America during the last thirty years as the study of these almost invisible organisms. Every advance in the knowledge of their structure or growth has produced the inquiry, Is this all, or is there something yet unseen? This could be answered only by producing lenses of better quality. The diatom cell is filled with the living matter of plants, endochrome and protoplasm, enclosed in a box of silica, secreted and deposited by the cell contents; this siliceous shell is its characteristic distinction from all other vegetable growths. The shells are beautifully sculptured with dots, lines, hexagons, and blank spaces, making them, as seen in the microscope, among the most beautiful objects of nature, always exciting an interest in those who see them for the first time, and in those who have made them the study of years.

They are found living abundantly in both fresh and sea water. Their dead siliceous shells are found under almost every peat bog; they are found fossilized in the Miocene Tertiary strata, in Maryland and Virginia, and in foreign countries; and when free from sand are used for tripoli, or polishing powder. The so-called electro-silicon from Nevada, is pure diatom shells. This article will be enough to answer the question, "What are diatoms?" but to learn more, the inquirer must first catch his microscope, and then study them in earnest.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ADVERTISEMENTS—30 cents per line.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Unavoidably Deferred.

WANT of space compels us to defer till our next issue several valuable and interesting articles, amongst others the following: "Description of the new Speech-Recorder;" "Measuring the Magnifying Power of Microscopes;" "How to Make a Cheap Condensing Lens;" "Practical Lessons in Photography;" "Turning Metals and Hard Substances," etc., etc. The April number promises to be specially rich in interesting and practical articles.

Our Journal and its Influence.

EVERY day proves to us that our journal is needed, and that it is calculated to do much good. The bane of this country is the prevalence of demoralizing juvenile literature. A few months ago a case was brought before the courts in New Jersey, where it appeared that a dozen boys, having given themselves up to the reading of "pirate" stories and story papers, actually leagued together and formed a robber band, having headquarters, watchword, signs, grips, etc. Although the children of respectable parents, wanting for nothing, they stole provisions, etc., upon which they feasted in secret, holding orgies modeled after those of robber chiefs!

The way to counteract this tendency is to give the boys (and girls too) something to do. The children of those who are above want may dislike to commence a *bona fide* trade; to them the YOUNG SCIENTIST will point a way to intelligent recreation and active employment. Those whose means are limited will find in our pages suggestions which will enable them to save or earn many times its cost.

Does not this subject deserve the attention of those parents who have the good of their children at heart?

A New Postal Law for the Discouragement of Science.

THERE is an old proverb, which says, "*Ne sutor ultra crepidam*,"—"Let not the shoemaker go beyond his last." Why the poor shoemaker should have been selected as the proper recipient for this advice, it has always exceeded our conundrum-solving powers to find out. Our experience has been that others are more apt to transgress this sound command than are shoemakers and kindred craftsmen.

For example: Here come seven wise men from Boston—publishers all—and they have taken it into their heads that they are the only class of citizens in the United States whose welfare should be consulted in the preparation of a postal law! In this they remind us of the goose in the well-known lines of Pope:

> "While man exclaims, 'See all things for my use!'
> 'See man for mine,' exclaims the pampered goose."

To the proposed law relating to the transmission of periodicals through the mails, no objections can be made. We ourselves have, in the columns of the *Technologist*, urged the adoption of every one of them, and they are good, even if they are not original with their present advocates. In this respect the proposed law is eminently just, simple and uniform in its provisions.

But why should seeds, specimens for scientific study, or samples of goods, be charged more than *Missionary Heralds*, *Atlantic Monthlies*, or *Golden Rules?* Do not flowers exert as elevating an influence as Boston transcendentalism? Do not scien-

tific exchanges and specimens promote the diffusion of knowledge quite as much as *Journals of Education?* And yet these Boston law-givers, in their egotism and selfishness, would absolutely exclude from the mails some of the most important means of diffusing sound scientific knowledge!

That nothing which can possibly injure mail matter or post office employees should be allowed to pass through the mails, is too obvious to require more than mere statement, and consequently glass vessels, liquids, pastes, sugar, explosives, etc., ought to be unmailable. But why a microscopic object-glass, securely boxed in its brass case, or the small slips of glass used for microscopic objects, should be so prohibited, we cannot see. In England, from whose laws this section is very closely copied, these things pass freely, and out of thousands of packages thus sent, none has ever caused any injury. But in this country, under our present laws which are not so strictly worded as the proposed law, the post office authorities at Washington have decided that the smallest fragment of glass, "even if enclosed in a cast-iron box and firmly screwed up, is unmailable."* According to this, even a finger-ring, having in it a tiny lock of hair, covered with a minute glass plate, is unmailable, lest it should injure the mails!!

It is true that hundreds of postmasters throughout the country cannot be convinced that such an interpretation of the law is not an absurdity, and they constantly admit glass slides and objectives to the mails. The Boston postmaster, who was consulted in regard to the new law, admits glass slides to his mails, but when they reach New York, our authorities charge them up at double letter rates!

If the proposed law should pass and be enforced, all scientific exchanges between students of microscopy will be stopped, and the seven publishers, through whose influence such disgraceful regulations have been enforced, will have their names crystallized in our scientific literature in no very enviable connection.

The list of substances excluded is indefinite, and consequently far too sweeping. "Poisons" include almost all our minerals, and very many of our finest flower seeds; "metallic substances" include a vast number of harmless and important articles. Under this law a lady could not procure by mail a sample of buttons, if they were made of metal or had metallic eyes! It may perhaps be objected that the authorities would probably rule that such articles are mailable, but the rulings previously quoted forbid this hope. Articles having "angles" are also excluded. Indeed it would be hard to find anything that would be mailable, except the products of these publisher's shops.

The fact is, that this whole section requires careful revision at the hands of business men of sound common sense. The authors of this bill tell us that it has been prepared "after consultation with publishers in different parts of the country." But other people besides publishers use the mails and contribute to the support of the government, and we regard it as a singularly unfortunate thing that the publishers of two religious journals, and one of them a regularly ordained clergyman, should have appended their names to such a thoroughly selfish document as the one before us. A proper liberality to other interests cannot possibly injure the publishers, and is but simple justice to the people at large.

*These are the exact words reported to us as the decision of the legal advisers of the Post Office Department. The best men in the country have argued and protested in vain against such rulings. But in the words of Schiller, "Mit der Dummheit kämpfen Götter selbst vergebens."

What Will the Weather be To-morrow?

EVERYBODY, from the child looking forward to the play hour, to the farmer or man of business whose livelihood depends upon rain or sunshine, is interested in the weather, and any means which will "foretell correctly any change in the weather twelve to twenty-four hours in advance," will be eagerly sought by a very

large number of customers. Undoubtedly the most perfect system of foretelling what the weather will be is that now in use by the United States Signal Service. The prognostications made by this system depend upon the observations of a very large corps of assistants scattered over the entire country. From the reports of these assistants as to the temperature, pressure, and hygrometric or moist condition of the atmosphere, and the direction and velocity of the wind at different points, tolerably reliable conclusions are reached as to the probable character of the weather during the succeeding twelve hours at any given station. Absolute certainty is, of course, impossible, and the published results have been given as "Probabilities" and "Indications."

But what neither "Old Probabilities" or "Young Indications" would venture to assume, is now fearlessly claimed by the advertisers of a very old and worthless device which has been recently manufactured in enormous quantities and sold at exorbitant prices, chiefly to farmers. We refer to the old weather-glass, consisting of a glass tube, filled with a solution of camphor and sal ammoniac in alcohol—and tightly sealed. Under certain conditions of pressure and temperature this solution becomes cloudy, and when these conditions change, it again becomes clear. Unlike a good barometer, it is easily made, not costing over ten or twelve cents when made in quantity, and when mounted in a cheap frame, with a twenty-five cent thermometer, it is sold for from one to two dollars.

In its very best form it was carefully investigated some years ago by several very able scientific men, and shown to be perfectly worthless. It is, in short, a worthy companion to the old almanacs, which professed to foretell, months and years ahead, just what the weather would be on any given day. It is generally advertised as a signal service *barometer*, but it is not a barometer in any sense of the word. It has more of the character of a rude *thermoscope*, or heat indicator, but as the walls of the glass tube are thin, they yield when the pressure of the atmosphere varies, and the solubility of the salts are somewhat affected by this fact. It is therefore a sort of nondescript, to which no really correct name can be applied.

It has been advertised largely in the agricultural papers, and has doubtless been sold extensively to farmers, having been freely praised, even by those papers that make a virtue of decrying all humbugs. And yet a more thorough and dangerous humbug has rarely been brought before the people, simply because it has all the appearance, without any of the reality of honesty.

We therefore add it to the Lefevre Diamonds and the Dollar Watch with "steel works," described in previous issues. In our next we shall take up a fourth humbug of a scientific or a mechanical kind. These so-called scientific humbugs are the most dangerous to the community, and the safest to the originators, and we propose to pay our respects to them *seriatim.*

Laboratory & Workshop

Making Glass Apparatus.

By Romyn Hitchcock.

Few things will give the young scientist more satisfaction than a set of instruments of his own make. Some of the most useful and interesting pieces of apparatus are made of glass, and therefore a few practical directions for working in this material will doubtless be acceptable.

We must caution our readers, however, that success in this work requires a certain dexterity which cannot be attained without a considerable amount of patience and perseverance. Failure at first is almost inevitable, but much of the difficulty vanishes when one has become accustomed to the handling of glass tubing, and has acquired the knack of heating and bending without fear of fracture and of blowing small bulbs on the end.

We must have a spirit lamp, or, what is far better, if gas can be used, a Bunsen burner, and for blowing glass we should have a good blowpipe worked by the foot, although a Bun-

sen burner alone will suffice if the gas pressure is good. A good blowpipe for heating glass tubes may be made out of some pieces of glass tubing, having a bore of about one-quarter of an inch in diameter. A description of such a blowpipe, which we have found to succeed perfectly in our own practice may not be amiss here. In Fig. 1, *a* is the top of a small stand, in fact, an old washstand, bought at auction, through which are bored four holes, *b*, *b*, *b*, *b*, somewhat larger than the glass tubes to be

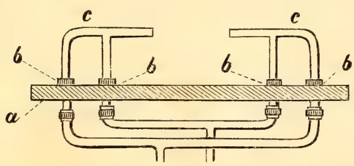

Fig. 1.

used. We select four pieces of tubing, two of them 6 inches long, and the two others about 11 inches. Join now a short one to the side of a long one, about 2½ inches from the end of the latter, so that the two will form a right angle; then bend the long tube down, and draw the short end off to a point to form the jet as seen at *c*. Do the same with the other tubes, and the two jets are made. They must be placed in the table, as shown in Fig. 1, by means of corks, which fit the holes in the table, the tubes being fitted into holes in the corks. Connect now the two inner tubes with the gas, and the two outer ones with the bellows, and the blowpipe is complete. There should be a stopcock between the bellows and each of the air tubes, to regulate the pressure. It is best to purchase a bellows, which can be had at moderate cost.

If the operator is not familiar with the method of joining a tube at right angles to another, he will perhaps find some difficulty in doing it, and will very likely prefer to simply *bend* a single tube at a right angle, and draw out a jet on one end. This will be his blowpipe, and the flame may be a common kerosene hand lamp, with a wick about half an inch wide or more, or what is still better a gas burner made with a flat top, perforated with numerous small holes, across which the jet is directed in the line of its greatest diameter. This top is well made oval, and about three-fourths of an inch long by half an inch wide.

In manipulating glass it is a great advantage to have two flames from opposite directions, which meet at an intermediate point, as much greater heat is at command, and the tube is heated much more evenly.

A few general directions for manipulating glass tubes are all that is necessary. To bend a tube, the best plan is to use a common fish-tail gas burner as the source of heat. The deposit of soot is an advantage in preventing too rapid cooling, and can be wiped off with a bit of paper or cloth. Let the tube be constantly revolving in the fingers while heating, and never attempt to bend a tube or *alter its form in any way while in the flame.* When well softened, remove from the flame, and bend slowly and steadily with the fingers at a moderate distance from the heated portion, so as to secure an even curve.

To make a good jet, or to contract the bore at any point, use the Bunsen burner, or, better, the blowpipe flame. Revolve the tube in the flame, and as it softens press gently together, so as to thicken the tube at the point heated. By a little practice a tube of one-quarter inch bore can be contracted to an almost capillary tube at any point, while the external diameter remains the same. To make a jet heat near the end and thicken in the same way, remove from the flame, and draw out slowly until the proper size is obtained. When the glass is thick enough we need simply heat and draw out, but usually the jet so obtained will have very thin walls, and hence be too fragile for service.

To blow a bulb is no easy matter at first. It is best to use a small tube with thick walls, draw it off abruptly at one end, and fuse it together. Then hold it in the blowpipe flame, and soften thoroughly, keeping the cool end down, so that some thickening shall take place. When properly heated withdraw from flame and blow quickly in the open end until the bulb is large enough. Never cease revolving in the fingers, or the bulb will be one sided. It will be one-sided any way until you know how to do it. To blow a bulb in any other part of a tube, follow the same general plan, and seal up one end or put a cork in it.

To make a "funnel tube," like Fig. 2, blow a bulb on the end of a tube, then revolve the tube in the flame, so as to heat the top of the bulb, down to the dotted line, *a b*. This

softens the upper part. Blow suddenly and forcibly, which makes the tube take the shape of Fig. 3. Break off the thin, kidney-shaped portion almost down to the line *a b* (Fig. 2),

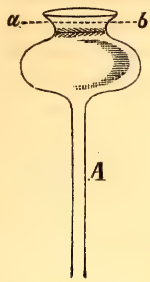

Fig. 2.

and round the edges by heat. Never use a tube for connections, or any piece of apparatus, until the ends are smoothed by heating in a Bunsen burner.

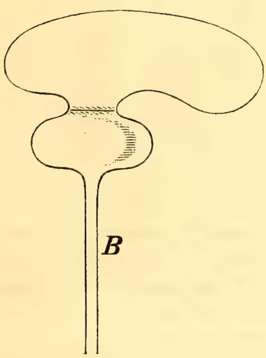

Fig. 3.

To join a tube at right angles to another, blow a thin bulb on the end of one tube, and break it off close down. This is merely to give an expanded end to the tube. On the other tube, at the point where the joint is to be made, heat intensely with a fine pointed flame, and blow out a hole in the side. The expanded end of the first tube will fit tolerably well over the opening thus made. Stop up two of the ends, leaving one open, and join the tubes by heat, blowing into the open tube to expand the joint as necessary. Do not make the glass about the joint too thick, and cool slowly. This is one of the most difficult operations to accomplish neatly, but it is of great value in many instances.

A Ten-Cent Galvanic Battery.

The interest which at present exists in regard to telephones, telegraphs, electroplating, etc., amongst young people, renders any simple and inexpensive method of constructing a galvanic battery a matter of great interest and importance to a large number. Some years ago we constructed a series of cells out of old tomato-cans, stiff brown paper, a little plaster of Paris, and some discarded sheet zinc that had served its day underneath stoves. The

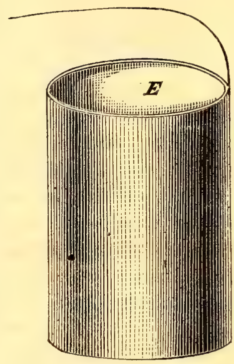

Fig. 1.

cost of the materials for each cell was but four or five cents, the cans being easily obtained for the picking up. In our present estimate of the cost of the battery, we place no value on the cans, for so long as canned fruits, vegetables and meats are consumed, the experimenter will be able to obtain this part of the apparatus without expense, and no fear need be entertained that the supply will fail, for our readers may rest assured that for every one who has brains and who will experiment, a hundred will be found who have stomachs and who will eat.

Besides the solutions, this battery consists of three parts: 1, the can, Fig. 1, which forms the outer cell; 2, the porous cell, Fig. 2; and, 3, the zinc, Fig. 3. The three parts are shown in section, arranged for work, in Fig. 4.

The can requires little or no preparation. It should be cleaned, the remains of the cover either cut off or hammered flat, so that the edge will be smooth, and a stout copper wire should be soldered to one side.

The porous cell is made thus: Procure a cylinder of wood or any other material about two inches in diameter; round it roll several

thicknesses of good brown paper, and "choke" the end a little with a cord, so as to make a contracted place at the lower end. The object of this is to prevent the plaster plug from

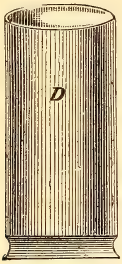

Fig. 2.

falling out, which it would do if the paper tube were smooth. Tie the paper firmly with twine, both where choked, and also higher up. Allow it to project about half an inch beyond the wooden cylinder, and in the space thus left

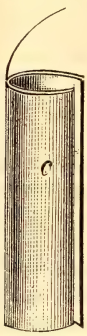

Fig. 3.

pour plaster of Paris mixed with water, in the same way that lamp dealers use it for fixing chimneys on lamps. When the plaster has set and become hard, the porous cell is made.

The zinc is simply a sheet cut to the proper size, and rolled into a cylinder. It may be amalgamated if the experimenter chooses, but works quite well without this. It must have a stout copper wire soldered* to it as shown in the figure.

The solutions required are a saturated solution of sulphate of copper (blue vitriol, a salt worth about 14 cents per pound), and a saturated solution of glauber's salts (sulphate of soda), to each pint of which two teaspoonsful of sulphuric acid (oil of vitriol) should be added. Arrange the various parts as shown in Fig. 4, where the battery is seen in section, the poles being connected by a fine iron wire which has just been fused. In this figure E is the outer can; D, the paper cylinder forming the

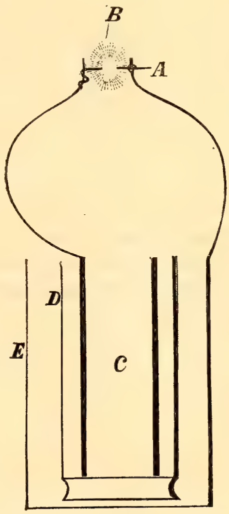

Fig. 4.

porous cell; and C, the zinc cylinder. Join the wire attached to the zinc to that attached to the can. The surfaces of the wires should be made bright where they come in contact, and they may be held together by means of a spring clothes-pin. Then fill the porous cell to within half an inch of the top with the solution of sulphate of soda, and fill the space between the tin can and the porous cell with sulphate of copper. A current of electricity will at once be set in motion, and after a short time, say, fifteen minutes, the interior of the tin can will have been completely coated with copper.

The reason for arranging the battery, and connecting the wires *before* pouring in the liquid is to give the can an opportunity to become coated by electro-deposition instead of by the chemical action of the sulphate of copper on the tin. The latter is apt to give a mere powdery coating, but the battery lays on a firm sheet of copper.

One such cell is capable of charging weakly

*The process of soldering is so frequently necessary, and it is also so simple and easily performed, that we shall give minute directions for performing it in our next issue.

an electro-magnet; it will burn off very fine iron wire (wire not thicker than a human hair), and will deposit a coating of copper on medals, etc. Two cells are comparatively stronger, and with half a dozen it is easy to send a current several hundred feet, and explode cartridges or burn wires. Such a series will make powerful electro-magnets, and will heat to a white heat a considerable length of fine platina or iron wire. It will also give quite a bright spark between two pieces of hard carbon, such as that from gas retorts. Thus, at an expense not exceeding fifty cents any country teacher who has a class in philosophy can get up a battery that will enable him to illustrate most of the experiments described in the books.

A Shower of Fire.

To those who see it for the first time, few experiments are more striking than the burning of iron, Iron is generally regarded as an incombustible substance; we make our pokers out of iron and not out of wood, because the latter burns easily, while an iron poker resists a very hot fire. Our stoves, too, are made of iron for the same reason, and when iron is seen burning fiercely it is a great surprise to most people. Dr. Priestly, the discoverer of oxygen, used to carry about with him a small flask of this gas for the purpose of amusing his friends by showing them the burning of a piece of iron, just as Wollaston, in after years, used to carry about a small battery made out of a lady's thimble, with which he was in the habit of exhibiting the ignition of a piece of very fine platinum wire.

There are several ways by which the combustibility of iron may be shown. The most common method is to set fire to a piece of watch-spring in a jar of oxygen. Another is to throw a jet of oxygen on a piece of cast iron laid on ignited charcoal. The iron fuses and burns with wonderful brilliancy, throwing off sparks until the effect is almost dazzling. We have fused as much as an ounce of metal at one time in this way. A third method is to drop iron filings into oxygen, passing them through a ring of flame, so that they became highly heated before they entered the pure gas. A fourth method is to support a mass of filings on the end of a magnet, and ignite them in a large jar of oxygen. The whole arrangement may be prepared in advance, and the filings may be ignited by passing a voltaic current through an iron wire which touches the filings. The combustion is exceedingly rapid and wonderfully brilliant.

The simplest method of showing the combustion of iron consists in suspending iron filings from the poles of a magnet, and setting them on fire with a common spirit lamp. They burn slowly but brilliantly in the open air, and as they keep falling from the magnet they form a remarkably curious and brilliant shower of fire. If the magnet be slightly tapped, the shower is increased, and if it be swung through the air a shower of fire is projected in all directions. Few experiments are more simple or more astonishingly brilliant than this.

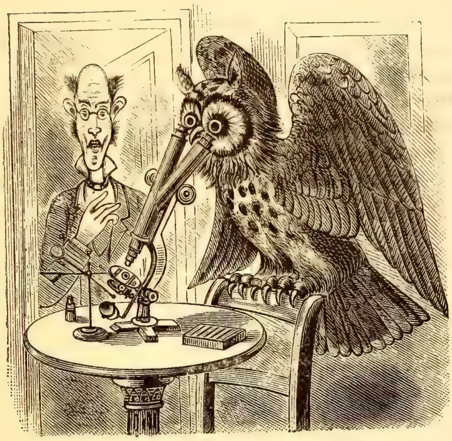
It is now nearly twenty years since this method of burning iron was described by Magnus, and yet even now it is not generally known. The reason for this is that although frequently described in books and papers, the points upon which success or failure turns has not been generally disclosed, and some of those who have understood it, have endeavored to keep it a secret. We have frequently exhibited the experiment in lectures, and sometimes, by means of electro-magnets, on a very large scale, and on every occasion it has produced a most profound impression.

The secret of success lies in the use of very fine filings. Over and over again parties have written to us, "We have tried your experiment with the iron filings, and have been unable to succeed." The fact was that they had gone to some blacksmith's shop, scraped up some of the iron filings from the bench, and used them. They might as well have used tenpenny nails. The filings must be of the finest kind, produced by the finest files. Iron in large masses resists fire very well; when in sufficiently fine powder it actually takes fire spontaneously, burning with great energy the moment it is brought into contact with the air. Fortunately, filings such as are necessary are an article of commerce, being manufactured extensively in Switzerland, and they may be procured from any large drug store.

All that is necessary is to dip a magnet in the filings, and lift as much as it will carry. The flame of a spirit lamp is then passed over the filings once or twice, so as to ignite them over the whole surface, after which they will continue to burn, and if held high and shaken, they produce remarkably brilliant effects.

We have performed this experiment upon every scale, using in some cases a small ten cent magnet, and in others a row of a dozen electro-magnets—the poles being wide apart, and the current quite strong. The magnets—were all firmly fixed to the same bar of wood, which was considerably elevated. When this bar was struck lightly with a hammer, a perfect sheet of burning iron fell down, and the effect was almost indescribable.

Microscopy.



Oh! my!!

What Power Shall we Use?

It is a very common error to suppose that in order to see anything clearly it is necessary to magnify it very much. Some things undoubtedly require very great magnifying power, but the majority of objects that are examined or studied by young microscopists are best seen with a moderate power. We must remember that when a very great magnifying power is applied to ordinary objects, we are able to see only a very small portion of them; no clear idea can be formed of the relation of the different parts, and the result is very unsatisfactory. At least 90 per cent of all the most interesting objects that are likely to present themselves to young microscopists can be seen very well by means of powers under two hundred diameters, and the range of objects that can be seen with a power of less than one hundred diameters is very large. Let us enumerate a few.

Almost all the opaque objects which are so celebrated for their beauty, can be seen with a power of twenty-five diameters. The list includes minerals, seeds, butterfly's scales, and other preparations of plants and insects. The general structure of plants, as shown by sections of stems, leaves, etc., is also well worth examination by this power. It will also show the general appearance of the larger animalcules, and of very many of the smaller larvæ of insects, as found in water.

A power of fifty diameters may be applied with good results to many of the objects just named. Such a power shows well such objects as the eels in paste, trichina in pork, the *Volvox Globator*, and many of the larger desmids and diatoms. The crystals of different salts, and particularly the active process of crystalization, are best seen under this power. The deposition of crystals of pure silver, obtained by decomposing a salt of that metal, is one of the most magnificent sights known to microchemistry.

With a power of 100 diameters, we can see the more minute structures of many of the objects named. Thus the eels in paste are seen not only as a whole, but their internal organs can be distinguished. We can also see the form of the blood corpuscles, and distinguish between the blood of the frog, the chicken and man. Some of the most wonderful sights can also be seen with this power, such as the circulation of the blood in the foot of the living frog. In short a description of the objects which may be profitably examined under this power would fill a large volume.

Paste-Eels.

Since the mention of these in our first number, we have had numerous inquiries in regard to the best means of obtaining them. It is generally said that if well-boiled paste is allowed to stand for some time, until it becomes sour, it will swarm with them. Such has not been our experience. During the summer we have kept paste until it attained every stage of decay, but no eels made their appearance, and we doubt very much if eels ever appeared in paste that had been well boiled, and had not been mixed with unboiled water. We have not been able to obtain them, except by the transfer of material known to contain them or their ova. These seems to be present in some samples of water, and when placed in paste they multiply with astonishing rapidity.

Paste eels are a very curious object under the microscope—indeed there are few objects that are more interesting to young people and beginners. They are easily raised and kept. Make a little well-boiled paste, and allow it to stand until sour. Add some old paste, containing eels, and in a short time the entire mass will be alive with them.

Our readers will doubtless ask, "Where shall we get the old paste?" We have plenty of it. Either call on us, or send a three-cent stamp, and we will

send you a sample by mail, enough to start with. Don't send stamped envelopes; also, prepare your paste before you send for the eels. The paste should be about as thick as cream. To examine them, mix a little of the paste with a drop of water on a glass slide, cover it with a thin glass cover, and place on the stage of the microscope.

Plants Growing Under the Microscope.

This is something that we read of in most books on the microscope, and although it is not by any means true plant growth, it is very curious and beautiful. Procure a little Collomia seed, which may be had from most seedsmen, but if you cannot get it easily, we will send you a few seeds, if you will send a stamp to pay postage. Take one of the seeds, and with a razor, or very sharp knife, cut off a very thin slice. Lay this slice on a slip of glass, (an ordinary slide), cover it with a thin glass cover, and, the microscope being in a vertical position, lay it on the stage. If you wish to incline the microscope, you must use a square glass cover, and not a round one, and hold the cover to its place by means of a very fine rubber ring. Now, bring the thin slice of seed into focus, and then apply a drop of water to the edge of the glass. The water will penetrate between the glasses and moisten the seed, which will at once throw out a very large number of spiral fibres—giving it the appearance of veritable germination. Beginners will find it easier to perform this experiment if one will apply the water while the other looks through the instrument. A single drop is enough.

A Sanguinary Hoax.

A few days ago a young man named Warren, of Jersey City, reported that he had shot a burglar who had dashed through the parlor window on to the porch, whence he had escaped to the street. Several spots of blood were found on the porch, which the young man insisted afforded a corroboration of his story. The police, however, suspected the truth of the young man's story, and therefore they had the blood examined by a microscopist, who pronounced it that of a bird. So this brave young man had to own that instead of killing a bold burglar, he had only killed a chicken!

Finishing Microscopic Slides.

Few things are more attractive, or afford greater pleasure to the owners than a cabinet of good slides, and the pleasure which they give is greatly increased if they are not only good as objects for study, but neat in appearance. Of late years the lides which have come most generally into favor are those of plain glass with ground edges. Paper covers are so apt to become soiled, worn and torn, that they are not much used. When uncovered slides with ground edges are used, the thin covers should be circular, and the edges, even where balsam is used, should be covered with a ring of varnish, put on with the turn-table. Some use varnish of very bright colors, laid on in rings. This looks very striking, and if the colors are well arranged they look very pretty, but one tires of them, and dull, quiet colors will be found to give the best satisfaction in the long run.

BOOK NOTICES.

The Amateur Mechanic's Practical Hand-Book. Describing the Different Tools required in the Workshop; the Uses of them and how to Use them; also Examples of Different Kinds of Work, etc., with full Descriptions and Drawings. By Arthur H. G. Hobson. Price $1.25. Philadelphia: Claxton, Remsen & Haffelfinger.

This is a small book of 114 pages, and is therefore rather a collection of useful notes upon the most important topics, than a systematic hand-book. The subjects which are discussed are: The Lathe and its Uses; Drilling and Planing Machines; the Vice, Bench and Hand Tools; Drawing and Pattern Making; the Brass Furnace and Moulding; How to Make a Horizontal Engine; Boilers. It is well illustrated, and the directions given are sound and practical. Amateurs will find it a useful assistant.

Robinson's Epitome of Literature. Monthly. $1 per year. Philadelphia: F. W. Robinson.

The extent of the current literature issued month by month is something wonderful. So great is it that no man can keep abreast of even the scientific literature of the day. It was therefore a good idea to give each month the chief contents of all the important magazines and journals published in the country, as well as a list of the books, with extended notices of the more prominent ones. In this way readers who have neither the money to spend nor the time required to labor through large piles of journals, are enabled to pick out what they want, to the exclusion of irrelevant matter. The journal before us is a welcome visitor to our table, and must prove of great value to every intelligent reader.

The Telephone. A Lecture entitled "Researches in Electric Telephony," by Prof. Alexander Graham Bell, delivered before the Society of Telegraph Engineers, Oct. 31, 1877. Price 60 cents. London and New York: E. & F. N. Spon.

Professor Bell here gives a very complete history of the telephone, and incidentally a very clear and succinct account of this wonderful invention. The lecture is very fully illustrated with wood engravings, showing the construction of the instrument at different stages of its history, and from these engravings it would be easy for any smart boy to go to work and construct a pair of telephones for himself. The pamphlet before us will prove of great interest, both to the general reader who desires to have clear and accurate ideas of the instrument, and to the amateur who desires to experiment.

Mechanical Work for Girls.

It is generally supposed that no woman can tie up a parcel, or sharpen a pencil. This we know to be a gross error. We have known girls who could handle most tools with quite as much dexterity as their brothers. A great deal depends upon training, and it will often serve a woman in good stead to be able to handle the hammer, the saw or the chisel. A recent writer in the "Country Gentleman" gives her experience thus: "Many a woman possesses as much ingenuity as a carpenter or cabinetmaker, and a little practice will teach her the upholsterer's trade, so that with nails, hammer, and the needful material, she will not only make as good a chair cushion as he, but will be able to cover a lounge respectably, and also an arm chair. Rocking chairs have often been far more comfortable than when first purchased, by the exercise of this art. In many families there are disabled chairs which have been thrown aside as useless, and yet, with but little expenditure, they could be made not only useful, but ornamental, and their presence would be a great addition to the sitting room."

Counterfeit Fossils.

A paragraph is going the rounds of the papers to the effect that the ingenious individual who manufactured the Cardiff giant, and the so-called Colorado petrified man, now comes with a startling story of previous exploits. He confesses to having manufactured the famous stone tablets of the Connecticut Valley, on which were imprinted by artificial means the tracks of supposed prehistoric birds—relics, which, it will be remembered, excited the whole scientific world. That he may have produced some of these tablets is quite possible, but, fortunately, of slabs of undoubted genuineness there has been discovered a number sufficient to sustain all the scientific theories that have been based on them.

Inquiries and Answers.

Inquiries.

3. Is there anything that will destroy the offensive odor of benzine? It is caused, I believe, by an excess of hydrogen gas. An answer to the above question will oblige. H. R. S.

4. Can any of the readers of the YOUNG SCIENTIST tell me how to preserve tadpoles while they are passing through the stages of transition to the frog? Last summer I tried several times to keep them alive and healthy, in order to observe the transformation, but always unsuccessfully, never succeeding in keeping them over a week. Fresh water, small pieces of rock, and liberal supplies of pond weed, were of no avail. An answer will greatly oblige. TRADDLES.

5. Can any of your readers give a simple direction for preserving lizards, frogs, etc., in alcohol, for future use; also, should they be disemboweled? AMATEUR.

6. Will some reader of this department inform me how to make a cement for joining glass to brass, and oblige. H. W.

7. Will some of your readers inform me of a simple dressing for meerschaum, with directions how and when to apply it, and oblige SMOKER.

Answers.

8. In answer to "Rustycuss," in the January number, I would answer him as follows, concerning the polishing of an old telescope. First, take it all apart, and polish well with the finest emery paper, rubbing only one way; then furnish yourself with a spirit lamp, a small quantity of shellac varnish, and a fine camel's hair brush (flat), and proceed to laquer it in the ordinary manner. This will prevent it from tarnishing for some time, but as time wears "on," the polish will wear off. BRASS BUTCHER.

9. In reply to "Rustycuss," I would say that if he will polish the brass work of his telescope, by running it very fast in a lathe, and applying very fine emery cloth or paper, until the desired end is produced; then warm the several parts or pieces carefully on a stove (don't get them too hot, only a little too warm to handle conveniently); then brush them over with the "Brass Lacquering" given on page 12. If well done the parts will look as good as new, and will keep a rich, clean appearance a long time. Microscopical apparatus may be finished and colored in the same manner. T. REST.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Two Selden's patent printing telegraph instruments; will exchange for microscope or books. Address W. Chamberlain, 446 Broome street, New York.

Specimens of the marbles, graites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

For exchange, for a microscope, a small engine lathe (screw cutting) in nice order, costing $110. Address Dr. J. H. Convurne, West Troy, N. Y.

Thorough and practical instruction in shorthand will be given in exchange for a microscope, with or without accessories, worth from $5 to $10. Address T. P. Wendover, 68 Christopher street, New York.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a good aquarium, medium size. State what is wanted in exchange. R. H., 8 Beekman Place, New York.

The Young Scientist

SCIENCE IS KNOWLEDGE. — KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

Vol. I. NEW YORK, APRIL, 1878. No. 4.

A Simple Musical Instrument.

SOME days since, having a few odd moments of leisure at my disposal, I set about arranging a curious little musical instrument on the kitchen table. A brief description of the little impromptu affair, together with an account of its wonderful capacities, will doubtless interest many of the readers of this journal, especially those who are musically inclined. Of course I make no claim to originality in the construction of this little instrument, and yet I don't know what to call it.

In making this instrument, the first step is to turn a tiny mallet, from soft wood, on the lathe. Make it about an inch in diameter, with the ends neatly convex, and with a light handle eight or ten inches long. Then pad and cover one of the ends with soft chamois or buckskin. Now get down the family goblets—your wife or mother may object, but you will not break them—and if you are fortunate enough to be able to make your selection from a fine set of Bohemian or cut glass, it will be all the better, as the finer and thinner the glass, the better will be the tone. Set your goblets on the table, and run over them with your mallet, tapping each gently to ascertain its pitch; then arrange them in a row, beginning with the lowest toned glass, and proceed upward, according to pitch. Now take the lowest toned goblet, and fill it with cold water, which will of course lower the tone still further, and give you the lowest tone of your scale. Then take the next lowest goblet, pour in water slowly, until the sound produced is precisely a semitone above that of the first goblet; and proceed in this way, regulating the pitch of each by the quantity of water, until you obtain a scale of one octave and a half, or two octaves, or as much more as the glassware at your command will allow. You

can, of course, leave some of the goblets empty, where the requirements of pitch make it necessary; and you will find this requisite in the highest tones at least. In fact the greatest difficulty is to obtain a sufficient range or compass of tone, unless you have goblets of varied size, shape and thickness. But, having your entire scale completed in regular chromatic succession, it will be well to go over it carefully, and see that all the intervals are musically accurate; for unless it be tuned nicely, the whole affair will be a noisy failure. Perhaps, however, I am assuming too much for the average reader, when I expect him to be able to set a musical scale successfully by his ear alone; and indeed this seems the more probable when we remember that not one out of five hundred musicians can tune an instrument at all. But in cases where the ear is thus deficient, the goblets can be tuned nicely by any keyed instrument that is itself in tune. In which case he has only to start at the tone indicated by his lowest goblet, and tune the succeeding ones in unison with those of the ascending scale of the instrument. In any event it will be found a fine discipline for the ear. Where the experimenter finds it impossible even to tune in unison, he had better direct his efforts in other channels of course. I am not writing for him.

Your tuning completed, the next operation will be to arrange your goblets to the best advantage, both for quality of tone and convenience of manipulation. To this end it is perhaps better to place your goblets on a long, inverted empty box, made of thin material, securely fastened together. Place the whole on your table, with the goblets arranged in the same order as the keys on a piano, placing the half tones, or sharps, corresponding to the black keys, slightly in the rear of the main line or diatonic scale, for the convenience of the performer—being careful that no two goblets touch each other; also that they rest firmly on the box, in order to avoid jarring. If your scale extends to two octaves, it might be well to arrange your goblets in two separate lines perhaps.

Now your instrument is ready, and you may take your mallet and play any air with which you are familiar, from a Sabbath school song to an opera. And my word for it, you will be surprised and delighted at the beauty and capacity of this little home-made instrument. The tones are very pure, limpid and mellow, and free from that metallic tendency so inseparable from all pianos. Of course much will depend upon the taste and skill of the performer, and some practice will be required to play rapid passages; but it is certainly susceptible of much variety and musical effect when properly handled. Shakes, trills, turns, runs, etc., are all within its scope, and only await the player's skill. The tone may be varied by the use of either the padded or the wooden end of the mallet, as the case may require. The glasses should be tapped on the outside, near the top. If it be desired to keep the instrument for any considerable length of time, it will be found necessary to re-tune it at intervals, as the tone changes by evaporation of the water. And if the water is left in a long time in a warm room, the tone will become deadened and spoiled. By having a mallet in each hand, two parts can be played at once, after some practice, and the harmony is very pretty. If the whole is properly constructed and well tuned, it will be found wonderfully melodious and effective.

H. Hendricks.

Kingston, N. Y.

How to Read a Drawing.

Continued from page 30.

IN the previous article we saw that neither a perspective view nor a simple plan will enable those who are not very expert to determine the exact dimensions even of such a simple object as two blocks lying one on the other.

Fig. 1 being a perspective view, and Fig. 2 a plan of two blocks, it is evident that it requires a drawing like Fig. 3* to give the precise thickness of the blocks. Such a figure is called an elevation, and these two

*The artist has, by mistake, drawn Fig. 3 with diagonal lines, as if it were a section. The shade lines should be perpendicular, like those in Fig. 6.

figures (2 and 3) are all that are necessary to enable us to reproduce the object from which they were drawn. The example that we have given is, however, probably the simplest that could have been chosen, and

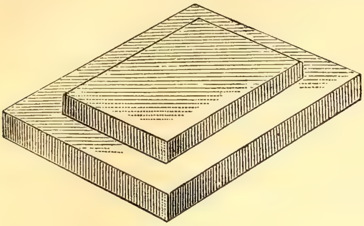


Fig. 1.

greater complication would have required a change in our method of drawing it.

Suppose that instead of two blocks lying one on the other, the object had been a block with a hole in it, such as is shown in

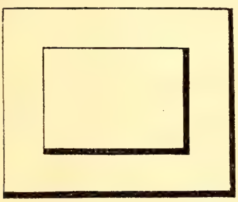

Fig. 2.

Fig. 4. A plan of Fig. 4 is given in Fig. 5, but a side elevation of Fig. 5 would be Fig. 6. This would give us the thickness of the block, and as the length and

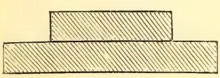

Fig. 3.

width of the hole are shown on the plan, it would be easy to reproduce the article. Instead of an elevation, however, most draughtsmen would give a section of

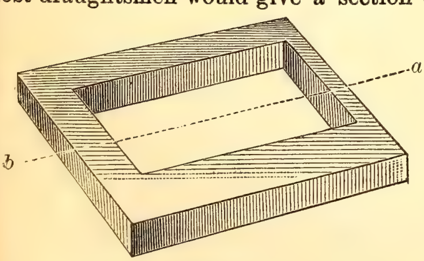

Fig. 4.

Fig. 5, as shown in Fig. 7. This shows the block as if it were cut in two along the line *a*, *b*, and the ends of the solid part of the block are seen *in section*, as it is called.

The reader will here notice that the lines on these different figures run in different

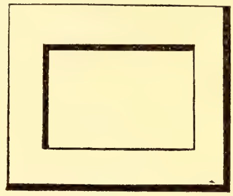

Fig. 5.

directions. The direction of each line is intended to express something. Thus, mere shading lines, like those on Figs. 1, 4 and 6, run either horizontally or perpendicularly. The lines on sections always run diagonally, making an angle of forty-five de-

Fig. 6.

grees with the perpendicular. Such a direction of the lines always indicates a section.

A section must always be carried through on a certain line. For example, as previously stated, Fig. 7 is a section on line *a*, *b*, Fig. 4. Everything through which the

Fig. 7.

line *a*, *b*, passes, is shown in section, as the reader will very clearly see. In some cases sections and elevations are combined. Thus, in Fig. 8, the parts through which the line *a*, *b*, passes, are shown in section, and the parts behind that line, and through which it does not pass, are shown in elevation.

Fig. 8.

The subject of sections is an important one, and will occupy our attention in the next article. We would again remind our readers that the object of these articles is not to teach the art of drawing, but to enable our young friends to understand drawings, and work from them.

Simple Lessons in the Art of Photography.

THE CAMERA.

THE camera obscura, or darkened chamber, is the invention of Baptista Porta, of Padua. Its principle will be easily understood by the very simple experiment of darkening a room and admitting a single pencil of light through a small hole in the window shutters. If a piece of paper is held at a little distance from this aperture, the figure of external objects will be seen delineated upon it. A lens placed in the hole will render the picture more distinct and brilliant.

A dark box may be substituted for the dark room, and the effect will be the same.

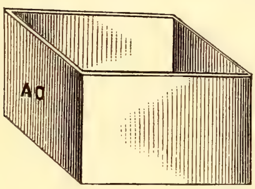

Fig. 1.

Fig. 1 represents such a box, A being the lens, and the opposite end the ground glass or oiled paper.

In the ordinary camera used for tracing the outlines on ground glass with a lead pencil, a mirror is introduced, which throws the picture upwards on the ground glass, placed horizontal, for the sake of greater convenience in drawing. Fig. 2 shows the section of a sketching camera. C is the

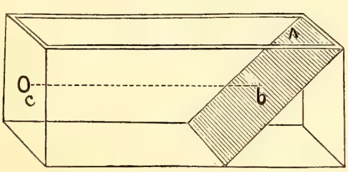

Fig. 2.

lens fastened in a sliding tube; *b* is the mirror placed accurately under an angle of forty-five degrees, or half a right angle; A is a piece of ground glass, which is removable. The focus of the lens must be equal to the distances A to *b*, and *b* to C. If, for instance, A *b* is 3 inches, and C *b* 6 inches, the focus of the lens for such a camera should be about 9 inches. The longer the focus of the lens, the larger is the picture on the ground glass. A lid may be used to exclude the light during sketching, but a piece of dark cloth one yard square will do it more effectually.

In photographic cameras the mirror is omitted, since its absorption of light would necessitate a longer exposure. Fig. 3 represents the simplest form of a photographic

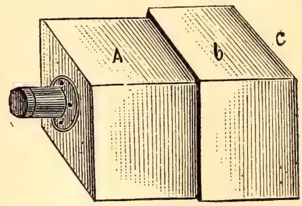

Fig. 3.

camera. It consists of an outer box, A, and an inner box, *b*; the latter slides in the former. The rear end, C, is especially adapted for the reception of the plate-holder. The plate-holder, Fig. 4, consists of a square frame, with a door on the rear

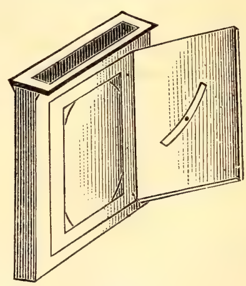

Fig. 4.

end, and a slide moving in grooves on the front side. The sensitized plate is placed on silver wires stretched across the corners of the frame, and kept in position by a spring fastened to the door. When bringing the object into focus, the front slide is removed, and a piece of ground glass is placed in the plate-holder, and the lens is moved forward and backward till a sharp picture is obtained. Cameras of better con-

struction, with bellows and focussing screw, are provided with a special frame holding the ground glass. The purchaser should always convince himself, by actual measurement, that the ground glass and the sensitized plate in the plate-holder occupy exactly the same plane. The construction of a photographic camera requires great skill and numerous tools, and therefore it might be advisable for the amateur to buy a ready made camera, with plate-holder.

Of simple lenses the plano-convex lens, with plane side towards the object, gives, after the meniscus with the concave side to the object, the most correct image. For landscape photography, simple lenses will do very well, lenses of larger diameter being preferable to those of a short diameter. For portraiture a combination lens, or portrait lens, is indispensable, though good results may also be obtained with a simple lens of large diameter.

The use of a simple lens always necessitates a small diaphragm or stop, in order to counteract spherical aberration and the want of achromaticity. Stops can easily be made of pasteboard to fit exactly into the tube of the lens. Fig. 5 represents a diaphragm. The projections, *a*, *b*, facilitate removing the stop. The centre of the diaphragm must coincide with the centre of

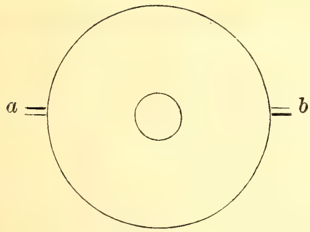

Fig. 5.

the lens. The position of the diaphragm, either in front or behind the lens, is immaterial, though a slight difference is thereby produced. Small diaphragms, that is, diaphragms with a small aperture (1-4 to 1-12 inch), increase considerably the depth of the focus, near and distant objects will be in focus at the same time, and the picture on the ground glass will be everywhere equally sharp. The disadvantage of a very small opening in the diaphragm lies in the fact that it diminishes the illumination of the image on the ground glass, and thereby renders a longer exposure necessary.

In order to ascertain whether the actinic and visual foci in a lens coincide, a thin piece of violet colored glass is placed before the lens, and the object is focussed on the ground glass. The violet colored glass is now removed, and if the image still appears sharp, the actinic and visual foci coincide. The visual focus is that distance between the lens and the ground glass which produces on the latter a sharp picture visible to the eye. A picture in the actinic focus may not appear sharp to the eye, and yet the picture will require a shorter exposure, and the negative may exhibit the most distinct outlines. The violet colored glass can just as conveniently be fixed permanently in the tube in front of the lens. For focusing, a piece of black velvet, or some other material impenetrable to light, about one yard square, is usually employed.

For copying pictures, the camera can be placed on a common table; for landscape photography and portraiture we need a tripod, which is easily constructed. A piece

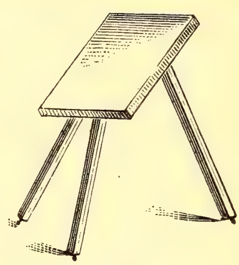

Fig. 6.

of oblong board, a little larger than the camera, is provided with three good hinges, one hinge in front, and one on each side, as shown in Fig. 6. Each hinge is fastened to a narrow slat of wood, which serves as leg. On the top of the oblong board you may nail some strips of wood, at such a distance apart that the camera can be tightly squeezed into them.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ALL COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

The Trial Trip.

WITH this issue the trial trip of many of our subscribers comes to an end, and of course we shall assume that those who fail to remit do not want the journal. To those who desire to continue with us, we would say that on receipt of the balance of the year's subscription—35 cents—their names will be entered for the year 1878.

We believe that we have kept the journal up to the standard of our promises, both as to matter and as to illustrations. Although we distinctly stated that we did not intend to make the YOUNG SCIENTIST a mere picture book, it has contained as fine illustrations as any journal of its class, and some that are far finer and more valuable than those which have appeared during the same period in much more pretentious and expensive periodicals. These illustrations have not been old electrotypes, purchased for a trifle, but new wood-cuts prepared expressly for our columns.

Of late we have had so much valuable matter on hand, that we have given four extra pages each month. Our readers will please remember that we do not promise this all the time.

The writers of almost all the letters that we receive say, "If you can keep your journal up to the standard of the number that I have seen, I will be a constant subscriber." In reply we would only ask our readers to examine our record. No. 2 was certainly an improvement on No. 1; No. 3 was better than No. 2; the present issue is equal to any that has gone before it, and we have in preparation material that will make the journal better and better as it grows older. But to make the journal all that we would like it to be, we must have a large subscription list—at least thirty thousand—and we hope our young friends will use their best efforts to bring this about. Let each one remember that every additional subscription enables us to give a better journal to those who have already subscribed.

That our success, thus far, is all that we could have desired, is evident from the fact that, although but four months old, we already have a larger circulation than any other scientific or mechanical journal published in this city with the exception of the *Scientific American* and the *Popular Science Monthly*.

The Right to Make Patented Articles.

TO those who comply with its provisions, the patent law of the United States secures the exclusive right to MAKE, USE and VEND any invention to which they can properly lay claim. And no person, not legally authorized so to do, can perform any one of these acts without laying himself liable to an action at law. Great doubt and confusion of ideas seem to exist upon this subject in the minds of many of our amateur mechanics and scientists, and even one of our mechanical monthlies, which makes great pretensions to being an authority upon *all* subjects, actually told its readers some time ago that any one had a right to make a patented article *for his own use!* It is unnecessary to say that this was an error, but

as in these days, when amateurs are making telephones, telegraphs, engines, etc., for their own use and for experiment, it may be well to tell our readers clearly and distinctly just how far they may go in this direction.*

The real state of the case, then, is that, according to the strict letter of the law, no person not authorized by the patentee or his representative, has any right to make a patented article for any purpose whatever. Those who make such articles are liable to be enjoined by the courts from further making or using them, if the patent has been properly sustained, and they are also liable to an action for damages. But unless actual damage has been inflicted upon the owner of the patent, it is very unlikely that *any* legal action would be taken, for if the patentee did take legal action, it would involve him in great trouble and expense, without any return whatever. This applies to cases where the advantages derived from the use of the invention are of a mere intellectual kind, but when the invention has been put in practice to the pecuniary profit of the infringer, damages may be collected, and a suit would probably be instituted.

Let us take the case of the telephone, for example. If some commercial or manufacturing house were to construct one or more pairs of telephones for the purpose of communicating between different parts of their establishment, they would be liable to an action for damages, because they would be deriving a substantial benefit from the use of the invention. But if some amateur were to construct a telephone for his own amusement, and for the purpose of studying the phenomena of magneto-electricity and sound, no damage would be done to the patentee, and as no court would award damages, it is not likely that the patentee would be so foolish as to institute a suit. If, however, these amateur telephones were used for purposes of public exhibition, the inventor would sustain damage, and would very likely bring a suit, since telephone exhibitions are an actual source of profit to the manufacturers.

It has been alleged that the use of an invention for scientific purposes is not an infringement in the legal sense, but this depends entirely upon circumstances. The whole question turns upon the amount of pecuniary advantage derived by the infringer, and the loss sustained by the patentee. We believe that even the use of an unlicensed telephone by a college professor, for purposes of public instruction, would lay him liable to an action; and since in this case the instrument is employed for pecuniary profit, its use is morally wrong, being in violation of the spirit of the contract existing between the public and the inventor.

Our readers will readily see then that whenever they construct any patented article, and apply it to any purpose which is to their pecuniary advantage, they commit a wrong legally and morally. But when the instrument is made and used wholly for intellectual purposes, and in such a way as not to work injury to the inventor, they are perfectly safe.

---

*In giving the advice which follows, we have considered not only the legal rights of the patentee, but the equitable rights of the public. Every patent is a bargain between the public and the inventor, in which the former agrees to give the latter all the profits arising from the invention during a certain period, provided the inventor will give the public the full benefit of all the knowledge and skill which he possesses in relation to the particular invention on hand. The fact that patents are always issued to the first inventor, and that there is scarcely any invention that has not been brought out at nearly the same time by several inventors, one of whom gets all the benefit to the exclusion of the others, constitutes every patent a species of robbery of all those who have the ability to devise for themselves, but who have not brought their inventions before the public. This partial evil and injustice must, however, be submitted to by the few for the good of the many. *Exclusive* property in any invention is therefore a legal and not a moral right. No man has a moral right to prevent me from using my brains in making any invention to which I am competent. It is only those who deal in buncombe who assert that any man has, on moral grounds, any *exclusive* right to his invention. The only rights that any inventor can have, if we exclude those which he obtains by law in virtue of his bargain with the public, is to practice his invention in security, and keep it secret as long as he can. But the people, having, through their representatives, agreed to give the patentee the benefits to be derived from the exclusive use of the invention during a certain period, are morally, as well as legally, bound to hold to this contract.

Miss Heller's Second Sight.

THE feats of an expert prestidigitateur have a charm for all ages. The young enjoy them in wonder and amazement; to those of riper years the methods by which the various feats are performed constitute a most interesting study; and the old enjoy them because they are made to feel young again. No wonder, therefore, that the exhibitions of first-class performers, like Heller, are crowded every night with a delighted audience.

The so-called magician has in all ages employed extensively the resources of natural science, and to-day the *seance* of any one who is more than a mere juggler, is a veritable exhibition of scientific wonders. Science alone, however, will not enable any one to become an expert, any more than a mere knowledge of the laws of electricity will enable one to become a good telegraph operator. All Heller's apparatus and all his knowledge might be placed at the disposal of his audience, and out of that crowd there is probably not one that would make even a tolerable performer. Great natural skill and long training have given Heller an ease of manipulation and a certainty of success which never fails to astonish, and when to this we add the attractions of geniality and *bonhomie*, it is no wonder that people crowd night after night to hear him.

Mr. Heller makes great use of electricity and electro-magnetism, and most of his feats are ingeniously conceived and very deftly performed. His windmill and miller are admirable pieces of mechanism, though we must acknowledge that this mechanism is almost too apparent. His pistol feat is good, but old; we have seen a much better and more astonishing method of performing the same trick. The transfer of the handkerchief to the heart of an orange which has developed on a tree in full sight of the audience is also very pretty, though perhaps a little too obvious.

To describe these and other wonders would, however, occupy too much time, and therefore we proceed at once to a consideration of the famous second sight, which has been for weeks the acknowledged attraction of his exhibitions. Now that Mr. Heller has withdrawn this feature from his performances, we will endeavor to explain how it *might* be done. There are several ways by which the same result might be attained; we will merely give that which seems to us best adapted to the end in view, and although it may not be the precise means used by Mr. Heller, it is certain that it is competent to perform all the wonders of the so-called second sight. Second sight, as exhibited by Miss Heller, has been frequently described in the papers. We will therefore give merely such a brief description as is necessary to an understanding of our explanation.

Miss Heller appears on the stage, and, after being blindfolded, seats herself on a lounge or sofa. Mr. Heller then walks amongst the audience, pointing to various articles, or touching them, and the lady at once, on the question being asked, not only tells what they are, but describes them. Thus, in the case of a fan, she not only tells us what the article is, but she further tells us that it is black, and that it has a tassel. A stick is described not only as a cane, but as brown and with a white top. Still more wonderful, one gentleman produces a watch, and she not only tells what it is, and what it is made of, but reads the time, details the figures engraved on the case, and even reads the motto—SINE TIMOR. Another gentleman produces a *shinplaster*, as it is called—one of those issued in an inland city—Rochester, N.Y.—in the early days of the late war. She gives the number, the value, the location, every required particular; and with peculiarly feminine *naiveté* she simulates an ignorance of the precise character of the articles, and of those features concerning which ladies are not supposed to be in general thoroughly informed. The little paper token she calls a thing like a bill, and articles of masculine property are described in the same vague way—all of which adds to the charm of the performance.

Several ways have been devised for car-

rying out this performance. Many years ago, Dr. Paris, in his well-known book, "Philosophy in Sport made Science in Earnest," detailed one of the best, but we are satisfied that the method described by Dr. Paris is not calcutated to give the exceedingly prompt and accurate results attained by Miss Heller. It is possible that several systems are used each evening, but there is one which is easily put in operation, and which is equal to all demands. This is the electric telegraph, and when we remember the extensive use made of electricity by Mr. Heller, we feel that it is more than probable that this is the agent employed. His miller, who opens and shuts the door of his mill, and throws out the cards, is electricity; the tree buds and the oranges are developed by electricity; the gun-cotton, which simulates the handkerchief that is supposed to be burned, is ignited by electricity; the half-dollars are dropped on to the glass stairs by electricity, and by the same agency they are allowed to fall into the body of the cash-box from a compartment in the side or top; the dropping of the curtains, and the firing of the gun-cotton in the medium scene, are also done by electricity. It is more than probable, therefore, that electricity is the chief agent in Miss Heller's second sight. But how is it applied? Mr. Heller carries no telegraph in his hand; he is perfectly free in all his movements; no wires seem to be connected with him in any way; how can it be done?

Nothing more simple. Proceeding from the stage might be two wires which pass underneath the carpets in the aisles to all parts of the house. These wires are connected with the tacks which hold down the carpets, and in this case these tacks do actually have large bright heads. Wire No. 1 being connected with one pole, and wire No. 2 with the other, each alternate tack is connected with a different wire. If, therefore, any two adjoining tacks be connected, the circuit will be complete.

To make use of this arrangement, the operator might have shoes or slippers with soles of wire gauze, or very thickly sewed with wire, or pegged with fine metal nails, and to these soles might be connected a wire which would pass up one leg of his trousers and down the other. Therefore, whenever the operator stood so that his feet rested on the heads of two consecutive tacks, the circuit would be complete. A small circuit breaker could of course be easily placed in one shoe, so as to be operated by the toes, and in this way telegraphic communication could be established with the stage, or the circuit breaker might be carried on some other part of the person. The receiving instrument on the stage might be merely a vibrating armature, the movement of which would be felt by the foot of the person on the stage, and several of these might be placed on different parts of the stage, so as to allow a considerable range of movement to the person who acts as seer.

Several circumstances conspire to convince us that this is the real solution of a problem which seems to have puzzled all our journalists. On several occasions, where Miss Heller has hesitated or made a mistake, the mistake has been just such as a telegraph operator would make in misinterpreting phonetic signals, such as "oysters" for "Austria." Moreover the answers often come too promptly to be explained on the system of verbal signals. It is probable that the required information is sent *before* the question is asked, and this renders the employment of the telegraph probable.

Taken all in all, it is one of the most ingeniously carried out arrangements that we have met in a long time. And like every part of Mr. Heller's performance, it is done with a dexterity and skill which renders it a pleasure even after we are fully apprised of the means employed.

— Education does not come through academies and colleges; these are helps, but it comes by study and reading and comparing. All the colleges in the world will not make a scholar of a man without these; and with them a man will be one if he never sees a college. It is that indomitable "I can" that sets a man astride the world.

Microscopy.

The Development of Frog Spawn.

IN a recent number of *Science Gossip*, Mr. A. M. McAldowie publishes the following notes on the development of frog spawn. A small quantity of this material, which will soon be abundant in almost every locality, forms a very interesting subject for observation under a low power. The following are the notes referred to:

"About the end of March, 1874 (exact date uncertain), I exposed a mass of frog's spawn to the light in a glass tank, placing it in a window having a westerly aspect. There was no fire in the room. The small round ovum (Fig. 1) gradually became elongated, assuming at first an ovoid form, but afterwards one end became attenuated, while a small groove formed near the other extremity, and on the 4th of April most of them presented the appearance shown in Fig. 2. As the embryo enlarged, these characters became more marked, until, on the 8th, the form of the head and the body could plainly be detected (Fig. 3).

"April 8th. Most of the embryos show signs of animation. The movements consist of alternate flexion and extension of the body, the animal folding itself up laterally and then straightening itself at intervals of about half a minute. Movements first observed in the afternoon, and continued till sunset.

"April 9th. Movements more active than yesterday, but still as restricted as before.

"April 10th. Movements not quite so quick as yesterday, but more extensive and fish-like.

"April 11th. Most of the tadpoles appear to be trying to free themselves from the albuminous mass by quick wriggling movements. External gills very plainly seen on all (Fig. 4). They first appeared as two small protuberances, situated one on each side of the hinder part of the head. These gradually elongated, divided and subdivided, until they presented the appearance of small branched filaments.

"April 12th. Tadpoles all out this morning. Arrange themselves in clusters with their heads all in one direction. Most of them remain quite motionless, but a few swim actively about the tank."

Fig. 1. Nat. size, March. Fig. 2. Ditto, April 4th.

Fig. 3. Ditto, April 8th. Fig. 4. Ditto, April 11th.

FROG'S SPAWN.

It will be observed that the figures are in pairs; in each case the left hand figure of a pair shows the dorsal aspect, and the right hand figure the lateral aspect.

Simple Hints for Beginners.

NO. I.

WE propose to give, from time to time, such simple elementary instructions in regard to the use of the microscope as will smooth the path of those who are commencing the study, and whose instruments are not of the best quality. It is all very well to say "don't buy a poor microscope;" suppose the reader has one of this kind already, and cannot afford to buy a better one—is it not better to work with a poor instrument than not to work at all? By keeping carefully within the bounds of what such an instrument can accomplish, it is wonderful how much it will show us.

One of the first things to be learned is the art of getting the object well illuminated. We must remember that the microscope is, after all, only an addition to the eye, and as the eye sees only by means of light, unless plenty of light passes from the object to the eye, we cannot see it. At the same time, we must avoid a mistake of exactly the opposite kind, and avoid getting too much light. The difficulty of reading letters which are written or engraved on bright metal strongly illuminated, shows the necessity for properly adjusting the amount of light to the circumstances of the case. As a general rule, the higher the magnifying power used, the greater is the amount of light required. With low powers—twenty to fifty diameters—even the cheapest compound microscopes will work with very moderate light.

The necessity for proper illumination is felt more in using the simple microscope than in any other. With very low powers, it is true, it is not difficult to see almost anything, but when the focal length of the lens is less than half an inch, it requires some care to prevent the frame of the glass or some part of the person, from shading the object, and in that case it will be impossible to see clearly. If the reader will carefully watch either his own movements, or that of a friend who is examining some opaque object with a simple microscope, he will soon see how want of care and skill in this respect prevents complete success. When the difficulty is once pointed out, however, it is easy to avoid it, and then we will be astonished at the wonderful improvement that our lens has undergone.

By means of good illumination, it is easy to see, with a power of ten diameters, things, which, with slightly inferior illumination, are quite invisible with a power of twenty-five. Indeed, good illumination will often supersede the necessity for a magnifier, and dissections and similar operations may be carried on better with the naked eye than with a lens. To prove this it is only necessary for the beginner to examine such objects as eels in vinegar or in paste. Place a drop on a slide, and look at it, without special illumination, holding it so that the ground or any dark surface may form the background. No eels will be seen. Now hold the slide against the light, and somewhat obliquely, and the eels will be quite distinct.

In the above case the objects are transparent, that is to say, we look *through* them, but the principle applies equally to opaque objects, or objects which we look *at*. Suppose we have a few portulacca seeds, one of the most beautiful objects that can be found. If we look at them through a cheap compound microscope—having merely laid them on a dark ground—they will be almost invisible. But if we throw on them a strong light, by means of a condensing lens, they will show with great beauty, even with a cheap non-achromatic microscope.

To be continued.

Trichina.

FROM several parts of the country there come to us reports of sickness and death, caused by the presence of these parasites. A gentleman who has been investigating the subject carefully, reports a very large percentage of the ham and pork in the New York market as being infected with trichina. Trichina are easily detected by means of a microscope of low power. The

cysts or capsules in which the "worms" are lodged may readily be detected with the naked eye, and a power of twenty diameters shows the worms themselves very plainly. The only way to avoid these creatures is to thoroughly cook any meat that may be eaten—especially pork or ham. Trichina are, however, sometimes found in beef, the cattle having been fed on grass manured with matter from slaughter-houses, and the pig pens attached thereto. In these slaughter-houses the rat is the greatest distributor of trichina. Rats are almost sure to get trichina from some of the flesh that they eat; while sick and feeble from the effects of this diet, they are apt to be caught by the pigs, in whom the trichina then multiply enormously. The extent to which rats and mice are infected with trichina leads to the further fact that most cats are so infected. We have in our possession several preparations made from different parts of the cat, and the muscles are all infected with trichina.

Laboratory & Workshop

How to Solder.

There are two ways in which this operation may be performed; one is by using the ordinary soldering iron; in the other the heat is obtained from a lamp. The first is the most workmanlike, and gives the best results, but the latter is most easily learned, and as any of our readers can easily manage to join pieces of brass, copper, tin plate, iron, etc., in this way, we will describe it first.

In soldering, the essential conditions are that the surfaces to be united shall be clean, and that they shall readily unite with the metal used for solder. All surfaces should therefore be scraped bright with an old knife, a file, a scraper, or even emery paper, but as they will not *stay* bright when heated, we must use something which will keep them so. For copper, brass or tin plate, resin is very good, but for other metals a solution of zinc in hydrochloric acid is best. Fill a small phial half full of dilute hydrochloric acid, put into it as much zinc as it will dissolve, and you have the soldering fluid, or liquid solder, which is now so much advertised, and which is sold on the sidewalks in New York.

The ease with which the different metals may be soldered is in order as follows: Tin plate, copper, platinum, silver, brass, wrought iron, steel, cast iron. We have heard some tinsmiths say that cast iron cannot be soldered, but this is a mistake; we have done it often.

The bright metal generally used for solder is an alloy of tin and lead—two parts of the former to one of the latter. A more fusible solder is sold in small strips at the hardware stores. A little bit of solder may, however, be obtained from any tinsmith, and will serve every purpose. Where solder cannot be had conveniently, tin foil, such as comes round tobacco, answers well. We have done a great deal of work with it. This tin foil is not pure tin, but consists of a sheet of lead between two sheets of tin, the compound sheet being rolled out thin.

For a lamp, anything will do. We have used candles and kerosene lamps, but greatly prefer a spirit lamp, as it is free from smoke and grease. An old ink bottle (one of the little triangular ones), with a hole through the cork, and through the hole a tube for the wick, does well.

Having procured the materials, let us now proceed to work. Suppose the job is to fasten a wire to a tin can for a battery. Scrape the end of the wire bright, and also scrape the tin; lay some solder on the latter; touch with a drop of soldering liquid, and heat over the lamp till the solder melts. The heat should be applied only to the spot where the solder rests. Dip the end of the wire in the soldering liquid, and as soon as the solder melts place the wire where it is to go, and hold it there till the solder has flowed all round it. Remove it from the flame and allow it to cool. It will be very firmly fastened.

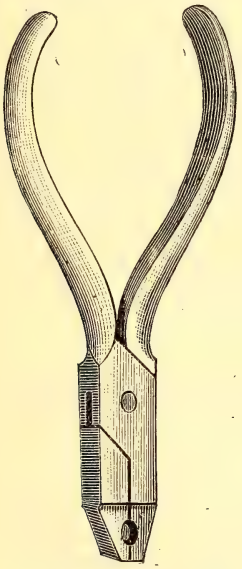
Suppose we wish to join two wires together. Hammer the ends flat, file them bright, lay them together, and bind firmly with fine iron, brass, or copper wire. Moisten with soldering liquid, lay a piece of solder on the joint, and heat in the lamp. When cold the joint will be very strong. By making a long splice, and filing off the binding wire after the solder has cooled, a joint may be made which will be scarcely perceptible, and yet be very strong.

Always, after using soldering fluid, wash off the joint carefully with pure water.

A very little experience will enable any one to join almost any two pieces of metal, and to solder a patch upon a metallic vessel.

Entomologist's Pliers.

Some time ago a friend showed us a very handsome pair of forceps, which had been made for the purpose of taking insects out of their cabinets and replacing them. In most cases insects are preserved by being impaled on slender pins, with heads like ordinary pins, and in order to examine any particular insect, it is necessary to pull the pin out of the cork lining of the cabinet. In doing this with the fingers alone, one is very apt to injure the insects on the adjoining pins, and therefore our friend had procured the forceps just mentioned. Such forceps, however, were open to two objections; they did not grasp firmly the



ENTOMOLOGICAL PLIERS.

round head of the pin, and the legs being levers of the wrong kind, the power applied was greatly wasted.

By taking a pair of common steel pliers, and softening the nose in the fire, a hollow may be filed in each blade, as shown in the engraving. This hollow receives the head of the pin, while the part just below the head is grasped with great firmness by a very slight exertion of power. By means of pliers fixed in this way, insects mounted on pins may be very readily taken out of their cabinets and replaced. The pliers may be rehardened if desired, and are then as good as ever for the purposes for which they were originally intended.

Tempering Small Steel Tools.

The art of tempering small tools is by no means difficult to acquire, and when we have learned to do it well, we can often save a great deal of time and trouble, by doing it ourselves, instead of having to go to a distance.

There are two distinct operations in the process of tempering. We must first *harden* the tool, and then let it down, as it is called, or soften it so that it will no longer be brittle, the rule being that a tool should be as soft as possible, provided it will keep its edge. Thus tools intended for cutting wood are always much softer than those used for cutting metal.

To temper a tool proceed as follows: Heat it to a bright red, and plunge the part to be hardened into water. We hear a great deal about *secrets* in the art of hardening, but they amount to very little. Some add salt, arsenic and other things to the water in which they harden steel, and claim to get much better results by so doing. The truth is that well boiled water is as good as any ordinary material. Fresh water has so much air in it that it will not harden steel well, because the air forms a thin coating on the steel, and prevents contact with the water, and the steel is a long time in cooling. Hence we find that blacksmiths like *old* water, that has been used a long time, for hardening. The reason is that the air has been all expelled, and if a little oil has been dropped in the tank, it will have kept the air out by covering the entire surface with a thin film. Small tools are sometimes hardened in mercury, and can be made very hard in this way. Small drills are often hardened by being heated in the flame of a candle, and then cooled by being thrust into the tallow. This answers well, but is no better than water. The mechanical journals often contain what is said to be a very valuable recipe for tempering, which is to plunge the heated tool into sealing-wax. This answers well, but has no special advantages. Very small tools and thin plates may be hardened by waving them rapidly in the air, and

it is said that some famous sword blades are tempered in this way.

No special skill is required for hardening small tools, but thin plates and large pieces require great care or they will crack or warp. They should therefore be handed over to some one of experience. Having hardened the tool, the next step is to *temper* it, since if left hard it would be brittle. It must therefore be heated until it has been sufficiently softened, and this varies with the use to which the tool is to be put. For drilling or cutting very hard substances, the temper should be high; soft substances may be cut with tools that are not so hard.

The degree of softness is judged by the color which the steel assumes when heated. A piece of hard steel, which has been made bright on a stone, becomes, during the process of heating, first straw color, then brownish yellow, then light purple, then dark purple, and lastly blue. The straw color, in its various shades, answers for tools intended to cut metal; tools for cutting wood should be brought to a brownish yellow; tools that are to be struck with a hammer should be made a little softer than those that act by pressure.

The temper of the cutting part may be let down in several ways, but the easiest and best is to cool or harden only the end of the tool, and leave the rest hot. In a few moments the heat will have been conducted from the hot part to the hardened part, and when the latter has assumed the proper color, the whole of the tool is cooled, and the tempering is complete.

Our Ten-Cent Battery.

The numerous letters that we have received, asking for further information in regard to this little piece of apparatus is evidence to us of the deep interest which many of our readers take in the subject, and we therefore answer in a general way the inquiries received.

The battery is simply a Daniel's battery, in which the tin can plays the part of both jar and copper sheet; the paper cup serves as a porous cell, and the zinc remains as in all batteries. The use of the wooden block in making the porous cell is simply to serve the purpose of a mould. If such a cylinder is not at hand, the paper may be rolled upon itself into a tube, three or four thicknesses of paper being used, and this tube being placed upright on a smooth surface (a board, for example), liquid plaster may be poured into it to a depth of half an inch, and allowed to set. And, by the way, let us say that the plaster is never used by dealers to fasten *chimneys* on lamps, as was inadvertently stated in our last, but to fasten the brass necks to the bowls. The object of the plaster is to form a heavy bottom to the paper cell. The wood is, of course, removed as soon as the cell is finished—that is, as soon as the plaster has become hard.

It is, of course, always better to amalgamate the zinc, especially if a durable battery is wanted, but very good results may be obtained without amalgamation. To amalgamate a new zinc, rub it with mercury and dilute sulphuric acid until it is as bright as a new dollar. When zinc, well amalgamated, is used with earthen cells and glass jars, the best liquid to use next the zinc is dilute sulphuric acid, but with unamalgamated zinc, paper cells and a tin can, it is best to use a strong solution of sulphate of soda, rendered very slightly acid.

The liquids must not be left in the battery until after the tin can has become heavily coated with copper.

Do not let the paper become dry, except after it has been washed out in clean water.

This battery is not a mere creature of the imagination. Some years ago we put together a considerable series, constructed substantially as we have described, and we obtained very satisfactory results.

Correspondence.

Iron Shot.

Ed. Young Scientist—In your article on iron bird shot, in the January number of your valuable journal, you say that, owing to the lightness of iron, shot made of that metal would reduce the range of a gun nearly one-half. It is evident that if the shot are made of such a size as to be of the same weight as leaden ones, the only loss of force would be that due to a slight increase of resistance of the air, owing to their greater size. Let us see how much this difference would be. As the specific gravity of lead is 11.25, and that of iron is 7.78, and as spheres are to each other as the cubes of their

diameters, knowing the diameter of a leaden shot, we can compute that of an iron one of the same weight.

Let us call the diameter of the leaden one 10: then the cube of $10 \times 11.25 \div 7.78 = 1446$; the cube root of 1446 is not quite 11.4, the diameter of an iron shot that would have the same weight as a leaden one whose diameter is 10. Now as circles are to each other as the squares of their diameters, the resistance of the air on an iron shot would be not quite 130, to 100 for the leaden one.

Now call the distance which a leaden shot will travel 10, then $10 \times 100 = 1000$, the total resistance necessary to stop either shot; $1000 \div 130 = 8$ nearly, so we see that an iron shot of the same weight would lack only one-fifth, instead of nearly half the range of a leaden one. This would be correct if nothing but the resistance of the air would tend to stop the shot; but as gravity would tend equally to bring both down, this would act to make both somewhat nearer equal. Now if, as is hoped, the iron shot would, by reason of not being flattened by crowding in the gun, scatter less, the effective range might be greater than with the leaden ones. Then there is the advantage of their not being poisonous to be taken into account. Birds have been killed by picking up shot, and a number of people were recently very seriously poisoned by lead absorbed by vegetables; cows are also said to have died from the same cause. H. A. Sprague.

Charlotte, Me.

Are Snakes Beneficial?

Ed. Young Scientist—I was much pleased to see that you have a good word for the toad, but as your article would seem to indicate that toads destroy mice as well as insects—which, if true, is new to me—I would ask if you meant to be so understood? You also say that we should cultivate the friendship of insectivorous reptiles—including the snake.

Now I would like to inquire if there is an insectivorous snake that does not also eat the toad? I and many others have seen snakes in the act of swallowing the toad. It is evident that snakes of this class ought to be destroyed, but there may be a purely insectivorous snake. If there is will you please describe it, so we shall know it from the harmful kinds.

H. A. Sprague.

BOOK NOTICES.

The Boy Engineers: What They Did and How They Did it. A Book for Boys. By the Rev. J. Luken, author of "The Young Mechanic," "Amongst Machines," etc. New York: G. P. Putnam's Sons.

The term "engineer," as used in this book, will, we are afraid, convey somewhat erroneous ideas to our American boys. The construction of engines and machines is certainly "engineering" in the strict sense of the word, but we are not accustomed to associate this term with the construction of wooden clocks and organs, or with the art of carving. Be this as it may, however, the book is a capital one. It details in simple language the work of two boys in making lathes, clocks, automata, engines, organs, apparatus, etc. It tells of their difficulties, and the means by which they surmounted them, and gives a great many very valuable hints and suggestions. Our readers, old or young, who may procure this book, have a rich treat in store for them.

United States Official Postal Guide: April, 1878. Price 50 cents. Boston: Houghton, Osgood & Co.

This valuable publication is published in pursuance of an express law to that effect, and with the authority and co-operation of the Post-Office Department at Washington. It contains an alphabetical list of post offices in the United States, with county, State and salary; money order offices, domestic and international; chief regulations of the Post-Office Department; instructions to the public; foreign and domestic postage tables; schedules of the arrival and closing of mails at the principal cities, arrival and departure of foreign mail steamers, with other information. It is absolutely indispensable to every man whose business involves the use of the mails.

A Lady Editor.—A mechanical journal is probably the last amongst the numerous periodicals now published that we would expect to find edited by a lady, and yet "The Mechanic," published at Smithville, N. J., is one of the most judiciously conducted journals of its class, and does great credit to the editor, Mrs. Smith. The terms are $1.00 per year.

A Call to the Telephone.—Several devices have been suggested for calling attention to the telephone, when it is desired to open conversation. Most of them are clumsy, and some require the attachment of a galvanic battery. One of the simplest is described and figured in "Nature." It is the invention of W. C. Rontgen, and consists principally of a tuning fork (Ut 4), one of whose prongs is brought close to one of the poles of the magnet in the telephone—preferably to the pole farthest from

the telephone disk, a straight or "bar" magnet being usually the kind used in the instrument. The tuning fork is mounted on a sounding board. Similar apparatus is provided at both ends of the line. To sound the alarm, in order to give a call of the telephone, it is only necessary to draw a fiddle-bow across one of the tuning forks; the other, at the further end of the line, responds with a note loud enough to attract attention throughout a large room.

Inquiries and Answers.

Inquiries.

10. Can any of your readers tell me how to make something to attach to my gas burner, so that I can light my gas with a battery. G. F. P.

11. As I was reading the last number of your valuable magazine, I came across an article on camphor barometers; and being desirous of making one, and not knowing the exact composition or proportions, I would respectfully ask you to inform me in your next number. G. Y.

12. If lead should be used for filling teeth, would it poison the gums? R. S.

13. Will you please inform me what acid will eat the vegetable matter from a green leaf, and leave the animal substance, making a skeleton leaf. J. F. M.

14. If you could tell me how to make a friction polish for turned work, to be applied in the lathe, such as we see on the wood on sale in the shops, I would be greatly obliged. The beeswax, alcohol, sandarac and turpentine formula, given in all the books, will not work with me at all. H. H.

15. Can any of the readers of the Young Scientist tell me how to mount objects for use with the Craig microscope. M. T. F.

16. What are Italian images and dolls made of? Also, how can artificial maple sugar be manufactured? +

Answers.

17. I do not know that my experience will be of any use to "Traddles," but it is rather interesting both as to how to keep tadpoles, and how not to keep them. Several years ago I had charge of an aquarium containing young tadpoles and several of our common fresh water fish—I have forgotten what kinds. The fish and the tadpoles agreed very well together. The tadpoles flourished, with no special attention, increased in size, and after due time developed their legs, and would no doubt have become good honest frogs—but then the fish eat them up. This was a phase of evolution that I had not before heard of. Carl Reddots.

18. In answer to "Amateur's" inquiry how to preserve lizards, frogs, etc., I beg to inform him that by using the "preserving fluid for scientific purposes," he can keep his specimens in their perfectly natural state, without any previous preparations. See advertisement.
Hermann Hurtzig, P. O. Box 4920, New York.

19. Some tadpoles seem to live largely or wholly on vegetable matter, chiefly the green matter that grows on the sides of aquaria exposed to the light. I have seen them *mow* this green growth off in circular sweeps, as if done with a miniature scythe. The tadpoles of some species of frogs feed on dead animal matter. Try them with a few pieces of meat. It is a curious fact that tadpoles kept in the dark do not develop into frogs. I have kept them in a dark cellar for two years, and they were still tadpoles; brought to the light they became frogs. Rana.

20. "Amateur" (letter 5) will find very complete directions for preparing and preserving material for dissection and microscopical examination in Rutherford's "Outlines of Practical Histology," pages 3–7. For mere preservation, Rutherford recommends proof spirit—our ordinary alcohol will do. Where the tissues are to be hardened, they are first soaked in a ¼ per cent solution of chromic acid—that is, one grain of chromic acid dissolved in 400 grains of water. Some portions of the animal are soaked in solution of common salt. The chapter is well worth the attention of "Amateur." Rana.

21. "H. W.," (letter 6) does not state the special object for which he wishes the cement. If he wishes to fix a flat piece of brass on glass or *vice versa*, good marine glue is the best thing he can get. If he wishes to fix a brass cap on a glass flask or tube, good red sealing-wax will do very well. The proper cement for the latter purpose is the so-called electrical cement. P. J.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Wanted, a xylophone in good condition; a Centennial jig saw, bought in December, in exchange. C. B. Culver, 131 East Seventeenth St., New York.

Wonderful magic tricks, to exchange for books, etc. Leonard Alexander, Linneus, Me.

Back numbers of the "Youth's Companion," for the years 1876 and 1877, cost $1.75 a year; lathe, for Centennial bracket saw; or "The Speaker's Garland," Vol. 2 or 3. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Two Selden's patent printing telegraph instruments; will exchange for microscope or books. Address W. Chamberlain, 446 Broome street, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Thorough and practical instruction in shorthand will be given in exchange for a microscope, with or without accessories, worth from $5 to $10. Address T. P. Wendover, 68 Christopher street, New York.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

The Champion Kite, and How it was Made.

BY JOSHUA ROSE, M. E.

ISN'T she a beauty?" said one.

"Dont duck a bit," said another.

"I know why she stands so still in the air," chimed in a third; "it's because the string don't belly."

"It don't stand *quite* still," remarked a fourth. "It moves slowly sometimes."

"Yes; but she don't keep wagging her head first to one side, and then to the other, as though she was playing bo-peep with her tail," was the rejoinder.

Harry Burt felt very proud to hear these remarks applied to his new kite, and showed his gratification by letting, first one and then another of his schoolmates, hold the string.

"Hurrah! Hurrah!! Hurrah!!!" rang out upon the air as the kite became invisible.

"Out of sight, by Jove!" cried one.

"She can't have broke loose," said another, half afraid that the kite *had* done so; "because the string is tight, and she is tugging away still."

"Run it down a little and see," said Harry. And away scampered one of the boys, with the thread of the kite passing through his hand, causing the kite to lower until it was again in sight.

"Let go," cried Harry, and the boy did so. Up shot the kite as straight as a dart.

But the rain soon began to patter, so Harry wound up the kite string, and walked home, surrounded by his companions, who never tired of praising his wonderful kite.

That morning Harry had stood looking, first anxiously out of the window at his playmates, who were flying their kites in the meadow, and then wistfully at his uncle, who was reading a book.

"What are you waiting for, Harry?" said his uncle, as he noticed Harry's furtive glances out of the window.

"I was watching my schoolfellows flying their kites," answered Harry hopefully.

"And wondering when I would make the one I promised you, eh, Master Harry? Well, fetch me the materials."

Harry bounded off, returning in a few minutes with a strip of pine wood and a piece of rattan cane in one hand, and a ball of thick twine and a sheet of pink tinted paper in the other.

"Shall we get it done to-day?" asked anxious Harry, as he laid the materials upon the table.

"That depends upon how our materials turn out. The first thing we must determine is to make the very best kite we can from the materials we have, and next we must try to make it as quickly as we can."

"What shape is it to be, Uncle?"

"A good question, Harry; and since you want the best kite, it must, of course, be of the best shape."

"But what is the best shape?"

"Let us see if we can find out. A kite flies when the pressure of the wind strikes it in a certain direction. You know this because of the position in which you fasten the twine to the belly-band. But let me make you a sketch that you may understand it better; there (Fig. 1) is a kite with

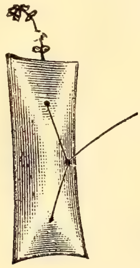

Fig. 1.

the string fastened to the middle of the belly-band. It stands, you see, upright, and the wind twies to blow it away without lifting it up at all; but if you fasten the twine higher up, as in this sketch (Fig. 2) the kite will stand aslant, and the wind will lift it. You see then, Master Harry, that it is the direction in which the wind strikes the surface of the kite that causes it to fly."

"Yes, Uncle, but if you fasten the twine as you have made it in the first sketch, the kite will sweep round and round, and sometimes come down head foremost."

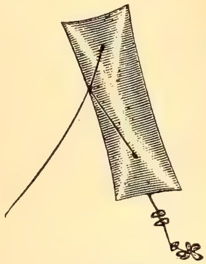

Fig. 2.

"That will always occur when the pressure of the wind is greater above the point of the belly-band, where the string is fastened, than if it is below. Suppose you were to fasten the twine below the centre of the kite, as in Fig. 3; then all the surface

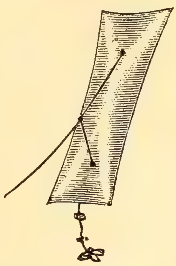

Fig. 3.

of the kite above the point where the belly-band is fastened, would be acted upon by the wind in a direction to keep the kite down to the ground, while only the surface from that point to the bottom of the kite can serve to counteract this, even when the kite stands upright; but when it slants over, as in Fig. 3, all the surface of the kite is being blown by the wind down towards the ground."

"But why should it sweep round and round, Uncle?"

"Because the surface above the fastening point of the belly-band tries to keep the top of the kite downwards, and the weight of the tail tries to keep it upright. The

gusts of wind strike the top a little more forcibly, and it begins to duck. You will notice that at every sweep or circle the kite makes, it gets nearer to the ground, and it usually strikes about head foremost. This is because when the head of the kite is moving on the downward side of the circles of its sweep, it does not feel the weight of the tail, and so moves very fast, while when it is sweeping with the top of the kite upwards it has to pull the tail after it, so it comes down with a spiral movement like this (Fig. 4), the head of the kite always

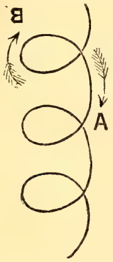

Fig. 4.

pointing downward on one side of the circles, as you see by the arrow, A, and always pointing upwards on the other side, as you see by the arrow, B. Now, if you notice, Harry, you will see that as the kite travels downwards on the A side, it must always strike the ground on its head or on its side. But your questions have rather led us away from the consideration of the shape of the kite, though in answering them I have shown you that the best shape will be that which will keep the surface of the kite as near flat as possible, while whatever bag there may be shall be in a direction to lift the kite, for you will notice that the bag of the face of the kite will always be in the same place, no matter where the string is fastened to the belly-band. Here is a kite of the square kind (Fig. 5). You see from the shade upon its face that its frame is composed of two pieces of wood, crossed at the middle, and supporting the paper across corners, so the paper between the supports bags or bends to the force of the wind. Now, look at the division marked 1, and you will see that its bagging throws its surface slightly in the direction of that of the kite shown in Fig. 3, and so tends to keep the kite from flying so well as it would

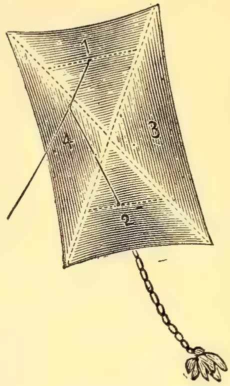

Fig. 5.

do if the bag was not there. The directions of the bagging of the divisions 2, 3 and 4, do not act to stop the kite from rising."

"What makes the face of the kite bag that way, Uncle?"

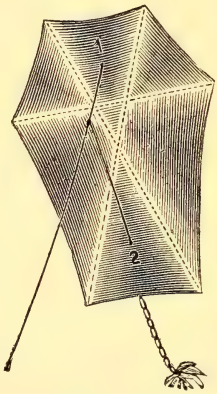

Fig. 6.

"Because the frame gives way to the force of the wind. In fact, Harry, it is a weak form of frame, depending only on the twine which ties it together to keep it in shape and stiff, and as the paper cannot be stretched tight on the frame, the bagging is sure to take place."

"Would a big square kite bag too?"

"Yes, and the larger the kite, the more it would bag in proportion."

"The edges of the kite you have drawn don't look square; what makes that?"

"Because you cannot take a flat surface and bend it in any direction without making its length or width smaller, so where the paper bags, the size across of the kite becomes smaller, and as this gives less surface for the wind to blow upon, the kite won't fly so well."

"Square shaped kites seem to have a great many faults."

"I haven't told you all yet, for the belly-

"Because they can be made easily and cheaply. Now, here (Fig. 6) you see is another shape of kite, each stick forming the frame being represented by a dotted line. See what a number of them there are—three in all; so such a kite must be heavy."

"Don't heavy kites fly well?"

"No, Harry; just think for yourself a moment. There is just so much pressure of wind trying to lift the kite, so the less the kite weighs for its size, the easier the wind can lift it."

"Why do they put tails on them; they weigh something?"

Fig. 8.

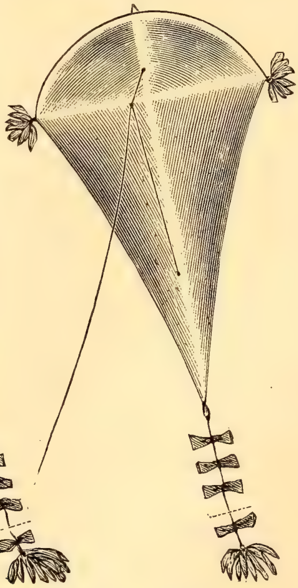

Fig. 7.

band must be fastened in the middle of the width of the kite, and as the frame don't come there, a piece of twine must be fastened across the frame, as you see by the dotted lines in Fig. 5, to fasten the belly-band to; then all the pull on the belly-band tries to pull the frame together, and this helps to make the kite face bag, and often causes the belly-band to tear the face of the kite by pulling the string, marked in dotted lines, through it."

"Why, then, do they make square shaped kites?"

"We shall come to that part presently; first let me call your attention to the fact that this kite still has the bag in the division 1, and lesser bags in the other places; and you remember that all the bag above the point where the string is fastened to the belly-band, acts to keep the kite down."

"What is the reason that the division marked 2 don't curve at the edge so much as that marked 1?"

"Because that marked 2 is kept straighter by the weight of the tail. Now, Master Harry, I have shown you some of the worst

forms of kites, and here is a sketch of the kite we are now going to make, which is one of the best, if not the very best we can select. One view (Fig. 7) is looking at the kite nearly full faced, and the other (Fig. 8) is looking at its side. The frame is composed of two pieces, one a straight piece, to which the tail is fastened at one end, while the other end, to which the bender is fastened, protrudes above the top of the kite in a point, as you see. The bender is a piece of rattan cane fastened near the top of the straight piece (which is called the standard), and bent around on each side, extending as far as the wings you see on each side. Now, look at the side view, Harry, and you will see that the bag of the paper is all in a direction to make the wind lift the kite."

"How large shall we make the kite, Uncle?"

"Let me see the twine you are going to fly it with, and then I will tell you. Oh, it is carpet thread, is it; well that is strong enough to fly a kite at least two feet high, so that shall be the height of *our* kite."

"Should the size of the kite be made to suit the strength of the string?"

"Yes, Harry, when you have got the string it should, because you can make the size of the kite to suit the strength and weight of the string, but you cannot alter the size of the string or twine. If you had not bought the twine, we could make the kite any convenient size, and then buy suitable thread or twine."

"Is it the size or the weight of the twine that is important?"

"First, Harry, the twine must be as light as possible, for it is a load that the kite has to carry. It must be strong enough to easily hold the kite, and it should be a closely twisted twine, so that it will not unravel and lose its strength, by being wound up and unwound."

"What part of the kite do you make first?"

"In everything that man constructs, Harry, the foundation or frame is made first. In this case it is the frame. Here we have a straight piece of pine wood for our standard; it is a yard long, and as we only want two feet of it, we must cut off one foot, and we will cut it off at this end, because it contains a knot that we shall then get rid of."

To be continued.

A Good Ten-Dollar Boat.

BY FRANKLIN VAN WINKLE, M. E.

WHO does not enjoy riding in a rowboat? It is one of those innocent pleasures which furnish healthful outdoor exercise, and is equally delightful to old and young, rich and poor. And how much pleasanter the sail when the boat is one's own, provided it be neat in appearance, easy to manage, and, above all, safe. There are many persons living near streams and sheets of water suitable for boating, who would be both benefited and entertained, during most of the spring and summer months, had they a nice boat at their disposal.

Keeping a boat is generally regarded as involving a great amount both of labor and expense; this is true only when its care is attended with bad management and false economy.

The best and safest boat is commonly known as a "round bottom." A good round bottom boat, however, cannot be purchased for less than seventy-five dollars, and such an outlay, especially in these times, is within the reach of but very few. The points of excellence in a pleasure boat are safety, strength, lightness and speed. The amateur boat builder might at first build a good flat-bottom, of which, by the way, there are but very few; and it is believed that if he diligently follows our instructions, he will be so successful as to attempt the construction of a round-bottom, after similar directions to be given at a future time.

To those who have been accustomed to see only the staunch and spacious jolly, or round-bottomed boat, or the light and graceful racing shell, the idea of the above qualities being combined in a skiff or skow,

may seem ridiculous. But recent experiments have shown that a flat-bottomed craft can be constructed which will surpass in speed yachts of the most improved lines, though they are by no means as elegant in appearance, and far more liable at a shift to capsize. The latter objection cannot be overcome in a sailboat of this description, for an increased breadth of beam makes her only the more difficult to manage—hence the usual remedy for round-bottom crafts would, in the instance of a flat-bottom, have just the opposite effect.

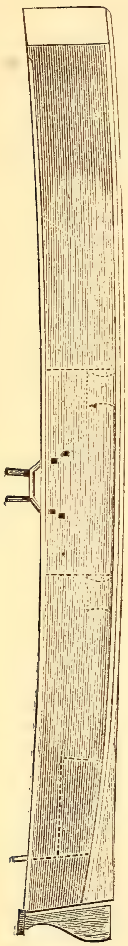

Fig. 1.—SIDE VIEW.

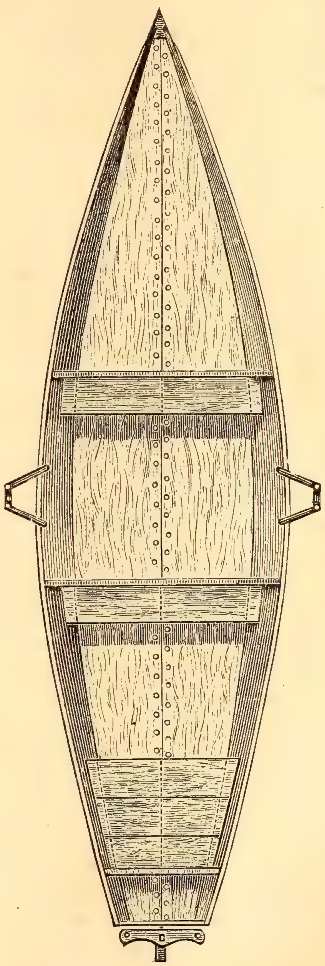

Fig. 2.—GROUND PLAN.

But for smooth water these objections do not extend to flat bottoms which are propelled by oars or by similar means, for, by proper proportions, ordinary workmanship, and a judicious selection of materials, a flat-bottomed boat may be constructed which will surpass the most sanguine expectations, even of its builder. Before the comparatively recent construction of sharpies, little or no attention was given to the proportions of boats of this description. After a careful consideration of the best method of constructing an ordinary sized boat, in which should be combined speed with lightness of draught, the following dimensions

were decided upon to carry two or three persons, though when built, this boat carried with safety nearly eight hundred weight.

the sides while the boat is in course of construction. Fig. 7 (see next number), longitudinal section through stem post or cutwater; Fig. 8, cross section through same.

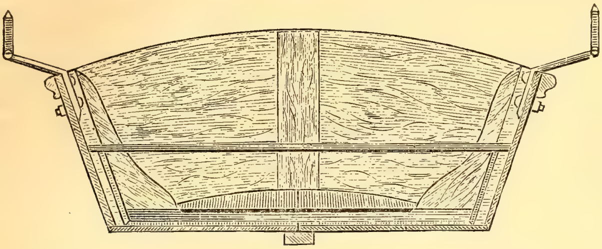

Fig. 3.—MIDDLE CROSS SECTION.

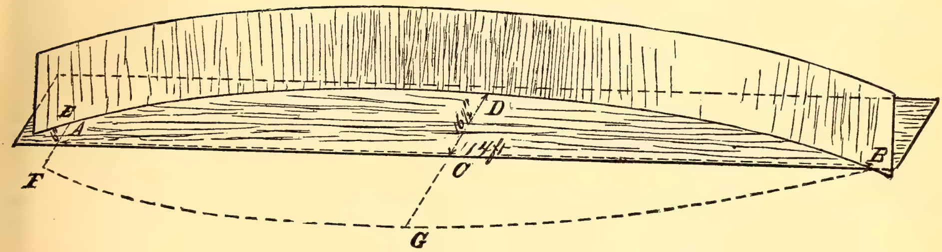

Fig. 5.

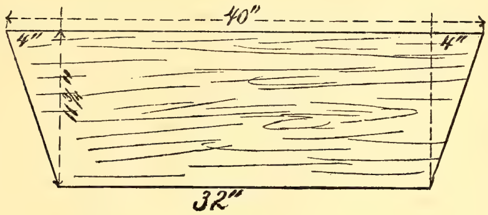

Fig. 6.

With the aid of the accompanying sketches and diagrams, we will proceed to describe this boat, and then give the method of its construction. Fig. 1 is a side view; Fig. 2 is the ground plan, and (upon a larger scale) Fig. 4, stern view, rudder removed; Fig. 3, middle cross section, looking forward. Fig. 5 shows method of marking out one of the bottom boards by the use of the other. Fig. 6 is a diagram showing shape and dimensions of cross-board used for a temporary brace between

Length over all (stem and stern)........	14	feet
Breadth of bottom at middle of length..	33	inches
Rake of sides (each) at middle of length.	4	"
Breadth of bottom at stern.............	12	"
Rake of sides (each) at stern............	1½	"
Depth of sideboards in main............	14	"
" " at stern............	10	"
Rise of stem and stern above gunwale at point of greatest flare................	6	"

The bottom and sides are of half-inch clear and well seasoned white pine, planed smooth on both sides. To insure symmetry and a better balance, both sideboards might

be sawed from the same plank and the same way with those of the bottom.

For the sides get two boards 14 inches wide and 16 feet long; and for the bottom two boards at least 15½ feet long by 17 inches wide. Laying down one of the bottom boards on an even floor, select two points (A and B, Fig. 5) 14 feet apart, the edge having been previously straightened and squared. Midway between these two points, as at C, scribe or draw a line square across from this edge, and mark a point, D, 16½ inches back from the edge, A, B. In the same way locate the point E 6 inches back from the point A. The points B, D

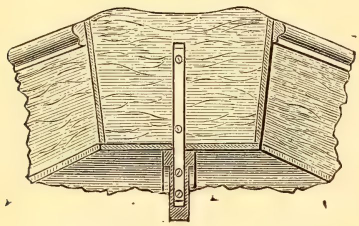

Fig. 4.—STERN VIEW.

and E being determined, stand the second bottom board on edge upon the first; bend it (dry) so that its lower outside edge passes through B, D and E. Then the curved board being held only at these points, mark the flat board around the outside of the curved one.

You now have the form of one-half of the bottom, A, B, D, E, which may be sawed out with a narrow cross-cut saw; and then, being trimmed with a smoothing plane, it may be used as a template or pattern for marking out the other half.

Laying these two bottom boards together, edge and edge, they will have the appearance of B, D, E, F, G (Fig. 5), which will be practically the same as the ground plan of the bottom, as shown in Fig. 2.

To be continued.

Popular Fallacies.

WE find the following paragraph going the rounds of the papers, and occupying a prominent place in the "Science Columns" of the religious and secular weeklies:

WHAT THE MICROSCOPE REVEALS.—1. Mold is a forest of beautiful trees, with branches, leaves and fruit.

2. Butterflies are fully feathered.

3. Hairs are hollow tubes.

4. The surface of our bodies is covered with scales like a fish; a single grain of sand would cover one hundred and fifty of these scales, and yet a scale covers five hundred pores. Through these narrow openings the perspiration forces itself like water through a sieve.

5. Each drop of stagnant water contains a world of living creatures, swimming with as much liberty as whales in the sea.

6. Each leaf has a colony of insects grazing it, like cows in a meadow.

It would be difficult to string together a series of sentences containing more errors. We have numbered each sentence, so as to refer to it with greater ease.

1. Mold is very beautiful, but the last thing to which it can be compared is a forest with *leaves*. Mold has no leaves.

2. Butterflies have no *feathers*. They are covered with scales, and these scales bear no resemblance to feathers.

3. Hairs are not "hollow" tubes. (Did the writer of the above ever see a tube that was not hollow?) Hairs are much more solid than a piece of ordinary wood. The popular mistake of supposing that hairs are tubes arose from the fact that every polished cylinder shows a bright streak down the centre when viewed as an opaque object. A common lead pencil shows this well.

4. The scales which cover our bodies are considerably different from fish scales.

5. This statement is more nearly true than any of those which have preceded it, and yet in regard to most stagnant water it is grossly exaggerated.

6. As regards the majority of leaves, the last statement is ridiculous. The expression, "grazing it, like cows in a meadow," is decidedly rich and laughable. Insects generally eat the leaf itself, they do not "graze it." But if the leaves are from healthy trees, our young friends may examine thousands of leaves with the microscope without finding a "colony of insects."

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ALL COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Summer Numbers.

DURING the next four months—May, June, July and August—we shall give special attention to matters connected with out-door studies, sports and pastimes, deferring such matters as chemical and electrical experiments, etc., until fall and winter.

In the present issue we commence two articles which cannot fail to interest our readers. The first is devoted to the kite, and gives very fully and clearly the scientific principles upon which that interesting toy should be constructed. From this point of view it cannot fail to interest older readers than those who usually construct kites.

The other article describes the construction of an easily and cheaply made, but very serviceable boat. The description is so full, and is made so clear by means of the engravings, that any intelligent boy who can handle a saw, a plane and a hammer, ought to be able to make one. The engravings and description are no fancy sketch, but are the details of the experience of one who actually made such a boat. The boat is now in use, doing good service, and the forms and dimensions laid down in the article are exactly those that were employed by the builder.

We have also in preparation two series of articles which cannot fail to interest a large circle of readers. The first is, "How to Begin the Study of Botany," and gives directions and hints for the use of beginners who are anxious to commence this study, but have no teacher. We have also in preparation a series of articles of a similar kind on entomology, so that our young friends who are collecting insects will be able to make an intelligent study of the subject.

We have also on hand other articles suitable for summer days.

Our Prizes.

QUITE a number of young people have gone earnestly to work to compete for the premiums offered in our March number. These prizes are all the very best of their kind, and our young friends may rely upon it that there will be perfect fair play. There is still abundant time for any active, earnest boy or girl to get up a good club, and stand a good chance for a valuable prize. This is more especially true, from the fact that some of those who have got up the largest clubs, being doubtful of their success, have preferred to make sure of the cash commission.

A Word to the Girls.

WE find that quite a number of young ladies have become subscribers to our journal. Of course, many of the subjects which we take up are of very little interest to them individually. Few of them, we fear, will care much for the turning-lathe or the vice-bench, though we know of several girls who have executed beautiful work with the scroll saw. It is true that some of our young lady friends take an interest in our articles for boys, because they learn from them how to give pleasure to

their younger brothers. For example, the article on kites has been inquired about by some of our lady subscribers, because they wished to find out the best way of making a kite to amuse some little boy. But we do not intend that the unselfish nature of the girls shall be taxed too severely, and we promise them important aid in their own special departments. Of course there is a wide range of subjects common to both boys and girls. Thus, the microscope, about which we shall always have at least a couple of pages, is used quite as frequently by girls as by boys, and often more efficiently by the former than by the latter. So, too, all subjects which merely give information, such as most articles on natural history. The care of pets, too, is often as great a source of pleasure to girls as to boys. But in addition to all this, we have made provision for special articles on subjects peculiarly interesting to girls, and such as they are not likely to find discussed in journals published exclusively for ladies.

Microscopy.

A Cheap Condensing Lens.

SUCCESS in the use of the microscope depends very largely upon proper management of the illumination. Some objects require a soft and subdued light; others demand the most intense illumination that can be obtained, and the various ways in which the light ought to be modified so as to produce the best results, are more numerous than most persons are aware of. Amongst the numerous accessories used for purposes of illumination, none are more useful, or give better results, than the condensing lens or bulls-eye condenser. And here let us explain the difference between these two: The bulls-eye condenser ought to be a hemispherical lens; a condensing lens may have any degree of curvature.

Until within a few months the condensing lens has been a somewhat expensive accessory, none being for sale at a less price than four to ten dollars. We have so often obtained really good results, however, by means of very cheap and simple arrangements that we shall describe a simple affair which we once made, and which seemed to work about as well as far more expensive articles. Any intelligent boy or girl can make one.

The thing that is required first is a suitable lens. We found that one of the best lenses for this purpose is what is called by spectacle makers a *cataract* lens, of as high a power as can be had; No. 2 answers very well. Such lenses have a short focus—about 2 inches—and are about an inch and a half in diameter. The cost varies from 15 to 25 cents, according to the profits demanded by the dealer.

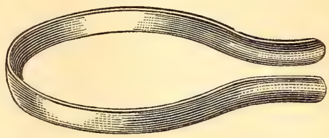

Fig. 1.

Where a cataract lens cannot be had, very good work may be done with some of the cheap lenses sold for burning glasses. In general, however, they have too long a focus. A good substitute for a lens is a small glass bulb filled with water. This we shall describe at some future time.

Having procured a lens, the next thing is to mount it. This is easily done. Get a common letter file, such as can be had for

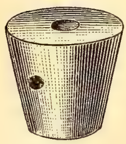

Fig. 2.

10 cents, or make one by inserting an upright wire in a block of wood, as shown in Fig. 3. Procure also a good bottle cork; a piece of wire about 6 inches long, and one-eighth of an inch in diameter; and a strip of tin about three-eighths of an inch wide and six inches long. Bend the tin into a loop, as shown in Fig. 1, the loop being the

exact size of the lens. The ends of the tin strip should be made narrow and hammered into a half-round form, so as to clasp the end of the wire, which should then be placed in the tube thus formed, and soldered there. A little care will be required in making the exact measurements, and fitting the loop so as to get it just the right size to hold the lens. If it should be a very trifle too small, the lens may be ground down on a common grindstone. If it be too large, it may be filled up with a second ring of tin, or even cardboard.

To fasten the lens in its place, various devices may be used. We fastened ours with sealing-wax, and it answers very well. This was done by heating the loop until it would melt the wax, and then coating the

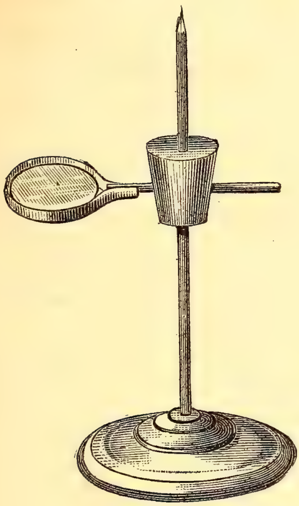

Fig. 3.

inside of it with that material. While the wax was still soft, the lens was pressed to its place, and the loop was again gently heated, so as to cause the wax to adhere to it firmly. A more mechanical and artistic method would be to get two rings of sheet tin, each an eighth of an inch wide, and of just such a size as would fit into the inside of the loop. These two rings are to be soldered to the loop, the lens being between them. Various other ways might be suggested, but the sealing-wax answers very well.

The next step is to connect the lens and its frame with the stand, and this is done by means of the cork. Two holes are bored through the cork, as shown in Fig. 2, one passes lengthwise through the centre, and the other hole passes through the cork at right angles to the first, and a little to one side of the centre. These holes can be made by means of a cork-borer, which is a small tube of sheet tin or brass, with the edges sharp; or they can be made by first passing an awl through the cork, and then enlarging the hole to the proper size by passing a red hot wire through it—an old knitting needle answering very well. As soon as the holes have been bored, the whole may be put together as shown in Fig. 3, and the condensing lens is complete.

The simplest and most obvious use of the condensing lens is to throw light (either daylight or lamplight) on opaque objects, examined by reflected light; and upon this and other uses we shall have a good deal to say in future numbers.

Correspondence.

A Fifteen-Cent Battery.

Ed. Young Scientist—Last year I constructed a cell of the carbon battery very cheaply. All that is needed is a glass fruit jar holding one quart, a piece of carbon (charcoal), and a piece of zinc. An old can will answer, or take a large quart bottle, and, with a glass cutter, cut the top off, which will make a good jar. You can get an old zinc at almost any telegraph station, or you can roll one out of sheet zinc, which will do as well. Make it 1 inch in diameter by 6 inches (or the height of can). Go to a tin shop and they will give you a piece of carbon (charcoal) same size as zinc; solder a good wire to the zinc, and drill a hole in the carbon and place a wire in it; place between the carbon and zinc a couple of pieces of rubber or wood; place a tight rubber band around them to hold them, and place them in the jar.

The solution is made by heating one quart of rain water to the boiling point, adding three ounces of bichromate of potash, and stirring

until it is all dissolved. Let it cool to blood heat; then add three liquid ounces of sulphuric acid. When cold it is ready for use. One cell of this battery is equal to six or eight tin can batteries.

This battery you can keep for years, and when you want to use it pour in the fluid and it is ready. It starts with full force.

H. A. KINNEY.

Hamlin, Kansas.

[The above is a very simple method of making a good battery, but it costs a good deal more than the tin can battery. Thin zinc does not last long in such a battery, and it is not always that a heavy zinc can be had for the asking. Well burned coke will be found to give better results than ordinary charcoal.—ED. A. J. M.]

BOOK NOTICES.

Hints to Plumbers and Householders. By W. L. O'Grady. With illustrations. New York: American News Company.

The numerous cases of sickness which have recently arisen from defective sewerage, many of them terminating fatally, has called renewed attention to the system of plumbing usually pursued. This little book explains the best methods of securing safety, and gives very complete figures of all the best arrangements in use. To the plumber it will be valuable, from the fact that it contains a great deal of useful statistical information and data in a compact form, while the householder must prize it from its clear and popular discussion of the general subject.

Exhibition of National Academy of Design.—The fifty-third annual exhibition of the National Academy of Design is now open, and presents a rich feast to lovers of art. It is generally conceded that the present exhibition exceeds in interest anything that has gone before it, and certainly many of the paintings now on the walls deserve hours and hours of continuous study. In the limited space at our command it would be impossible to enumerate even the most prominent paintings on exhibition, while to single out a few would be invidious. We trust, however, that many of our young readers will visit the exhibition again and again, to see them and study them for themselves, for we know of no way in which a few evenings can be passed with greater pleasure, and certainly of all the exhibitions now open to the public, none has a more elevating tendency. It is hardly necessary to say that the rooms are at the corner of Fourth avenue and Twenty-third street.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

A good telegraph instrument, cost $7 50, for a couple of good books on chemistry, electricity, etc. H. B. Kinney, Hamlin, Brown County, Kansas.

Wanted to exchange, a stencil outfit for a Barnes' scroll and circular saw, foot power; or a good battery for electro-plating; or an artificial incubator; or state what you have to exchange; reason for exchanging is the partial loss of right arm; all letters answered, Barton A. Whitsett, Box 115, Lebanon, Ind.

A large number of minerals and fossils for exchange. Persons wishing to exchange please send list to W. H. Hughes, 47 Jeff. Avenue, Grand Rapids, Mich.

Wanted in exchange for a second-hand scroll saw, treadle power and wooden frame, a good Excelsior microscope, or live box. Jos. G. Thorp, 54 West Seventeenth street, New York.

A set of chemicals and apparatus; also a set of wood engraver's tools, glass and instruction book, to exchange for a scroll saw and a microscope. The chemicals and tools cost nearly $40; will give a good trade. F. H. Jackson, Angelica, N. Y.

To exchange, a Pope's air pistol for a set of carving tools. L. Y. R. G., Box 317, Brookfield, Mass.

Cigar machine to exchange for bracket saw or good microscope. Leonard Alexander, Linneus, Me.

Wanted, a small turning lathe in exchange for a pair of telephones. J. C., care YOUNG SCIENTIST.

Magic lantern, nine slides (two mechanical) in complete order, in exchange for good compound microscope. T. R. Barwood, Flatbush, L. I.

A work on painting and wood finishing, value $1.50, to exchange for scroll saw patterns. R. F. Hanscam, North Barnstead, N. H.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

Wanted, a xylophone in good condition; a Centennial jig saw, bought in December, in exchange. C. B. Culver, 131 East Seventeenth St., New York.

Back numbers of the "Youth's Companion," for the years 1876 and 1877, cost $1.75 a year; lathe, for Centennial bracket saw; or "The Speaker's Garland," Vol. 2 or 3. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Thorough and practical instruction in shorthand will be given in exchange for a microscope, with or without accessories, worth from $5 to $10. Address T. P. Wendover, 68 Christopher street, New York.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

VOL. I NEW YORK, JUNE, 1878. No. 6.

How to Study Entomology.

BY F. C. SMITH.

I.

In presenting a series of articles on the study of insects, it is hoped that an interest will be created among our young readers that will lead them not only to the collection of specimens and filling of cabinets, but also to study their habits and transformations.

Of late there seems to be an increasing interest taken in this, one of the most absorbing branches, of natural history.

In the following articles care will be taken to use terms that may be readily understood by those who we hope will be interested, and drawings of the necessary apparatus will be rendered as simple and easily made as possible.

Butterflies and Moths.—For these a net will be indispensable, though for taking moths that fly by night, of which there are many varieties, they may be taken in a trap which we shall presently describe.

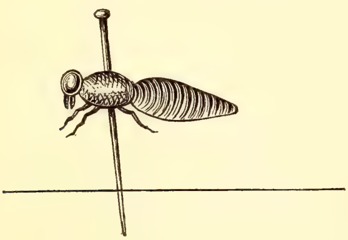
The Net.—For a net a simple wire hoop about twelve inches in diameter is best, fastened to a pole five feet long, which should be light enough to use with one hand, as occasion will require. Telegraph wire may be used, though a size larger is better. The ends should be bent to run down the sides of the pole four or five inches. It can be fastened by winding tightly with fine wire, or a blacksmith will form a shank on the hoop for a few cents. To this hoop should be sewed a bag of Swiss muslin, tarlatan, or mosquito-netting, about twice as deep as the diameter of the hoop; or a border of strong cloth may be sewed to the bag, and this to the wire. In using this net, when you have caught your specimen, give the net a half turn, and you have it a prisoner in the fold hanging over the wire. The same net is used for all insects that are caught on the wing.

The Collecting Box.—A large flat cigar-box makes a convenient receptacle for all insects

that require to be pinned. A better one is made by using two cigar boxes, fastening the lids together with short screws. A cushion or piece of cork for pins should be fastened at one end of the box. As the specimens must be made secure, it is a good plan to line the box with sheet cork, or melted beeswax, to prevent bending the pins by pressing into the wood. The whole may be suspended from the shoulder by a cord, or fastened by a strap to the waist. The pockets of the collector should at all times be well stocked with pill boxes, of different sizes, in which may be placed any odd specimens that are sure to turn up when least expected.

Stupefying.—After catching a butterfly or moth, it should be given a dose of ether or chloroform (sulphuric ether is best), of which the collector should carry a vial. A penny paint brush stuck in the cork is handy and prevents waste. By touching the mouth of the captive with the moistened brush, it will at once become happy and entirely oblivious to the operation of pinning, which, if done without stupefying, is both cruel and inconvenient.

Pinning.—Now take your specimen from the net, and, holding it by the under side of the body, in the fingers of the left hand, thrust the pin in at the centre of the thorax (the second division of the body), and out



between the second and third pair of legs, as seen in the cut. Some moths will bleed a little when first pinned. A piece of blotting-paper will quickly absorb the blood, and prevent it soiling their plumage. The specimen may now be pinned in the collecting box, and if after a while it revives, apply another dose of ether, thus keeping it from fluttering, and insensible to pain.

Killing.—Some prefer to kill specimens as soon as caught, by the use of a wide-mouthed cyanide bottle, small enough for the pocket. To make this, procure at the druggists one or two ounces of cyanide of potassium, and powder it. Put two or three layers of the poison into the bottle, with pieces of blotting paper between the layers, and one piece cut a little larger than the inside of the bottle, to put over all. Press this down firmly, letting the whole fill the bottle about one-quarter full. For home use, a jar the size and shape of a candy jar, with a wide mouth, may be prepared, of course using more of the poison. Keep this well corked or covered, as the fumes are very poisonous. Into this jar put any specimens that are brought home stupefied with ether. No harm will be done if insects are allowed to remain in the jar over night—in fact they will become pervaded with the poison, and it will tend to preserve them.

Setting.—When taken from the jar, they should be immediately set on the mounting board, as shown in another article in this journal. They must remain set until rigid, requiring from two or three days to a week, according to the size. The wings must not droop; if they do, let them remain longer on the mounting board. In setting butterflies and moths, never put a pin through the texture of the wings. A needle driven into a penholder may be used to manipulate the wings, holding them forward with pins driven in the board.

The primary (forward) wings should be carried forward enough to show all the markings of the secondary (back) wings.

The fore feet, tongue and antennæ may be arranged according to fancy, and they will always remain in the position in which they dry.

Entomological Pins.—These are manufactured especially for the use of collectors, and may be obtained from dealers in naturalist's goods. They are made long and slim, that the specimens may be set well up

from the bottom of the cabinet case, the reason of which will be told later. Two or three sizes will be needed for butterflies, moths, beetles, crickets, grasshoppers, bees, wasps, etc. For mounting smaller insects, another method will be explained in our next.

Relaxing.—Sometimes a specimen, overlooked, or presented by a friend, becomes rigid, or has its wings closed, and it becomes necessary to relax it before it can be set. This may easily be done by pinning the specimen to a cork, and on this let it float in a dish of water, covering it with a damp cloth. Damp sand covered with blotting paper will serve the same purpose. From four to eight hours will suffice, as a longer time tends to cause mold. Specimens may thus be set as easily as when just killed. Mold may be destroyed by brushing the insect with benzine, to which a little creosote has been added.

General Hints.—For handling insects, a simple pair of tweezers will be convenient; also the pliers described on page 57 of the Young Scientist. After removing butterflies and moths from mounting board, they should be stored in a dark place until the cabinet cases are ready to receive them. Tight boxes must be used for storing, as specimens are liable to be attacked by a small beetle or fly, which will eat away the body of a large moth to a mere shell. A fine dust under the insect will betray its presence. A piece of gum camphor should be placed in storing boxes.

Record.—A record should be kept of all specimens, giving each a number, and entering this number in a blank book ruled to record number, name, locality, date, donor or collector, and notes concerning capture, etc. The numbers may be home-made, or library numbers can be bought in sheet form for a trifle. Keep each number with its insect, on the same pin if desired. The Latin names may be filled in the record at any time afterward.

There are several good text books on entomology, with which all insects may be named and classified. The editor will at any time advise as to what works are preferable.

In our next article we will give directions for sugaring, also design for a moth trap.

To be continued.

The Champion Kite, and How it was Made.

By Joshua Rose. M. E.

Concluded from page 65.

"WHAT difference does the knot make, Uncle?"

"The stick is weaker where the knot is; we want our standard strong and light, and so even in strength that it will bend with an even curve throughout. There, now the end is cut off, and we must cut the stick down to the proper size. You see it is crooked, and in paring it down we must straighten it. Every now and then, you see, I stop paring it, and lay it down upon the table and turn it over and over, to see where it is crooked, and then pare off the high places. Here, you see, is our standard (Fig. 9) all ready; it is made with flat

Fig. 9.

sides, because we can more easily make it straight, and it will hold the bender more firmly. It has a small notch at the top for the twine that binds the bender to fall into, so that it can't move, and a little notch at the bottom for the string from the end of the bender to fall into, as you will see presently. Now for the bender, which must be rather shorter than the standard, say one-

sixth shorter, so in this case it must be 20 inches long. It should not have a knot or joint in its entire length, but, as we cannot find that length clear of a joint in this piece of rattan cane, we will let a joint be in the middle of its length, where it won't interfere with the bending. This, you see, is the straightest part of the cane, so we will cut it off 10 inches on each side of this joint.

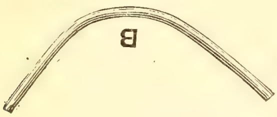


Fig. 10.

Now we must go to work and split the cane, for it is too thick and heavy, as it does not require to be more than the thickness of a slate pencil at the ends, and a little thicker than a lead pencil in the middle. There, you see, it has split pretty even, and now we will round it up."

"Why do you make it smaller at the ends, Uncle?"

"To make it bend with an even sweep. Let me show you on this spare piece of unsplit cane; there, do you see (Fig. 10) how uneven it bends, and how ugly or misshapen it seems. This is because the ends are too strong to bend, so we must make them weaker by tapering them off, and the more even we taper them, the more even or regular the bend will be. Now we have pared them down nearly small enough, we will straighten them by laying, one end at a time, on the table, to see where the high or protruding crooks are, and scrape them away with our penknife. Now, you see, they look alike, but we must test our work; so let us find the middle of the length. We cut off this piece of twine to the full length of the bender, and then bring the ends even and double it up. Now place one end of the doubled twine at the end of the bender, holding it straight along the bender, and where the other end comes is the middle of the length of the bender, so we cut a small notch there to mark it. Now rest the notch on the back of the penknife blade, so (Fig. 11). You see it does not quite balance, so we must take more off the heavy side, and try it again. Now you see it pretty nearly balances, so it will do for the present, but let us notice which is the heavy side, for that knowledge may be useful presently."

"What difference does the balancing make?"

"If one side is heaviest, it will cause the kite to lean over on that side, and, in all likelihood, that side is the thickest, and won't bend so even. In that case there will be more face on the kite on one side of the standard than on the other, and then the wind will put more pressure on that side, and the kite will wag, or sway about, when you fly it."

"I didn't think it took so much care to make a kite."

"It does to make a good one, that will fly high, keep steady, and look stately.

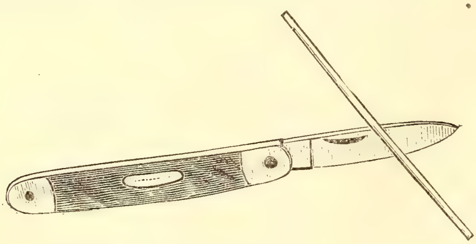

Fig. 11.

Now let us tie the bender to the standard, taking care to tie it exactly in the middle, where the notch is. Here it is (Fig. 12), you see, all ready to bend. Now we make a fine notch close to each end of the bender, and tie a string or twine to one end, then pass the other end round the other end of

the standard, and up to the other end of the bender, drawing it tight, so as to spring the

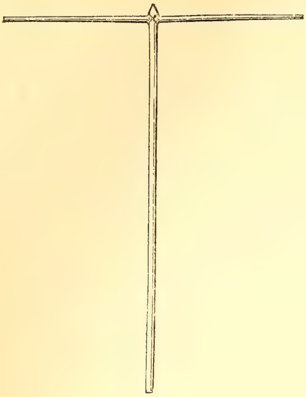

Fig. 12.

bender to a bow shape, just as you see in Fig. 13. Now you see that one side is bent more than the other, the side A being the least bent. Now, let us see if that isn't the side that was a little the heaviest when we balanced the bender. Yes, it is; I thought so. Now we will take a piece of sandpaper and reduce that side a little, and that will

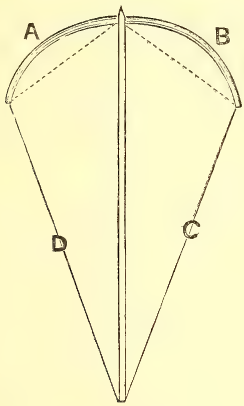

Fig. 13.

make the bend and the weight both right. If you want to see how much it is out of true, just look at the distance between the dotted lines and the bender on each side. Our sandpapering you see has made it just right."

"But suppose the bender had been exactly balanced, and then didn't bend right, Uncle?"

"I am just coming to that, Harry. You see that, in Fig. 13, one side of the bender is marked A, and the other B, while the string bending it is marked C on one side and D on the other. Now the lengths of C and D must be just equal, and we make them equal by slipping the twine in the notch, which, you remember, we made in the end of the standard, that is at E. When we have made them equal, we tie the twine tightly to the standard near the end E, using another piece of twine, and letting its ends hang down in a loop to tie the tail to. Next we take a piece of twine and tie it to one end of the bender, drawing it just tight, but not enough to bend the bender, and fastening it to the standard, where it meets the bender—that is, it will occupy the position of one of the dotted lines in Fig. 13. We next fasten another piece the same way on the other side, and then, instead of the dotted lines, we shall have pieces of twine. If one side of the bender wants a little more bending, we must draw the piece of twine last added a little tighter, and if this slackens one of the lines C or D, we must tighten the latter again. We next take another piece of twine and tie it to one end of the bender, draw it just tight enough to feel the strain, and pass it straight across to the standard, tying it there; then pass it straight across to the other end of the bender, draw it just taut, and tie it there; and then our frame is made."

"Is there any way of testing if it is the right shape and evenly balanced?"

"Yes; here is our kite frame (Fig. 14) all finished, and if you measure and compare the length of A on one side with that of A on the other, you will find them equal, and so it is with the lines B on each side, and the lines C—all are of equal lengths, while C on each side is an equal distance from the curve of the bender. This proves that the frame is even shaped, and so there is as much surface, for the wind to strike against, on one side of the kite as there is on the other. Now for the balance; all we can do

is to place a loop of string around the standard at about the place where the line B B is tied, and hold the face of the kite horizontal; then we may move the loop along the standard to balance its length, and see if one side always droops when the kite frame is put slightly in motion by the finger. If it does, that side is heaviest, and

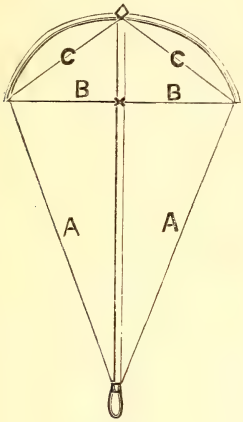

Fig. 14.

we must turn over the edge of the paper more on that side when we put it on, so as to balance the weight."

"It is a pretty looking frame."

"Yes, and what is better, it is a firm one, for the tension of the bender keeps it stiff, while it also causes the bender to keep all the strings tight."

"How is the paper put on?"

"Smooth it out flat upon the table, and cut it out, leaving a nice edge to turn over; cut notches out of the paper, to let each end of the bender, and the point at the top of the standard, come through. Then paste the edges of the paper and turn them over all round, taking care not to double the paper over too far, which would set the side strings out of straight. The kite being dry, we may put the wings on the end of the bender, as you see them in Fig. 7."

"What are those wings for; to make the kite look pretty?"

"They do add to the beauty, but they are not put there for that purpose altogether. You must know, Harry, that wind doesn't blow evenly quite, but comes in gusts, and when the wind strikes on one side of the kite stronger than it does on the other, it makes the kite sway to one side. The wings, you observe, are made of a piece of paper formed like a tassel. Suppose, then, that the wind is strongest for a moment on the right hand side of the kite, the ends of the wings are blown more behind the kite than those on the left hand side, so that the side of the kite that has the least pressure of wind on it, has most of the wing exposed to the wind, and this makes up for the less pressure, and so keeps the kite steady."

"What kind of tail shall we have?"

"Let me tell you the use of a kite tail. Many boys seem to think that the weight of the tail is what is required, but that is quite wrong, for the weight is only *one* consideration. Do the best we can, we cannot keep the kite quite steady, unless the wind blows very evenly on each side of it, which is not very often the case, and the kite always moves towards the side where the wind blows the least. To partly prevent this, we want the tail to present a good deal of surface to the air, and this will make it harder to move through the air. If you fold up a fan, you can move it very quickly, but if you open it full out, it is more difficult to move it, although its weight is the same in both cases; just so it is with a kite tail—whatever its weight may be, it will take more time to move it through the air if it presents a large surface than if it presents a less one. An easy way to get a large surface is to cut some pieces of newspaper about three inches long and an inch and a half wide, and fold them up lengthways until they are only about half an inch wide. Then make loops in a piece of twine, and fasten these pieces of paper, which are called spills, in the middle, placing them along the twine about three inches apart, and making the tail about four times the length of the kite, and putting a paper tassel on the end."

This is how Harry got the champion kite, and how it flew is told at the beginning of this story.

A Good Ten-Dollar Boat.

BY FRANKLIN VAN WINKLE, M. E.

Concluded from page 68.

THE only part of the construction requiring any degree of carpentering skill is the cutwater or stem post. This should be made next. A piece of hard wood (ash is preferable) is first cut in the form of a wedge, the angle between the sides (A, B, C, Fig. 7) being made the same as the angle between the edges of the bottom board at the point B, Fig. 5. The breadth of this wedge is equal to the main width of the side boards (14 inches) added to the thickness of the bottom (½-inch), viz., 14½ inches, and the length along either side from its point, *i. e.* from B to A or C, is equal to 6 inches. The grain may run either vertically or horizontally. Next cut, in the sides of the wedge, gains half an inch deep by 3 inches broad, as A, D, Fig. 7, in which to drop the ends of the side boards, and make them flush with the original wedge, as indicated by the dotted lines. The stem piece will then have a cross section similar to the shaded part of the figure. In the same way as for the sides, cut a step into one end of the stem post in which to drop the bottom boards, leaving them projecting about an inch forward of the joints at the ends of the side boards.

Next fit the side boards to the stem post. Cut them off on a bevel, making them 1½ inches longer on the upper edge. Fasten them to the stem piece with 1¼ inch No. 13 screws. Then remove one side, bend the other around the curved edge of one of the bottoms, and find by trial *about* where the

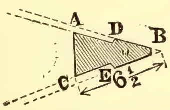

Fig. 7.—HORIZONTAL SECTION THROUGH STEM POST.

stern comes. Beginning about 3 feet forward of the stern, sweep a curve up from the bottom edge, gradually growing steeper towards the stern *at* that point, so that the side board is left 9 or 10 inches deep. Cut the curve only, and use this side board as a template after which to shape the other. The ends must not be cut off until after the stern piece has been set in position.

The side boards are then to be soaked in water for about twelve hours previous to bending. This may be done either by sinking them in water, or by winding around them wet carpets or cloths. While the sides are soaking, cut from three-quarter inch or 1 inch stuff, a cross board of the dimensions given in Fig. 6, and have this in readiness to bend your side boards around. After sufficiently soaking the sides, put them back in the stem post; then, with the stern piece resting on the point of the bottom boards, tie the sides together at the stern. Midway between stem and stern, *i. e.* where G, D, of Fig. 5 comes, insert the cross board longest side up. In this form give them at least twenty-four hours in which to take a set, but do not allow them to stand in the sun, as in that case they will be liable to twist.

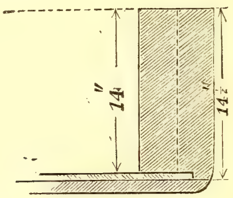

Fig. 8.—LONGITUDINAL SECTION THROUGH STEM.

The sides, after drying, being set out the proper distance apart at the stern, and tacked there, the bottom edges are planed to receive the bottom. The proper bevel is found by simply laying a straight-edge across, care being taken not to plane below the inside edges.

The bottom boards are now fitted to their seat in the bottom of the stem-post, laid in their proper positions, and, beginning at the bow, are permanently fastened with fourpenny nails to the sides.

The stern piece should then be cut from one-inch plank, and, as shown in Fig. 4, set inside of both side and bottom boards, with a

rake on each side of 1½ inches. Fasten from outside with 1¼ inch No. 9 screws, about 2½ inches apart. As there will be considerable additional strain at the upper edge of the side boards, in consequence of their flare, they should be stayed by a quarter-inch bolt passing clear across the stern, against the inside of the stern piece.

The keel, which is 1¼ by 2 inches in size, should now be fastened to the bottom. Commencing at the bow, it is first fastened to the under side of the stem piece, overlapping the joint made by the bottom, as shown in Fig. 8, and then fastened to the bottom boards from the inside, with 1½ inch No. 13 screws through the bottom, alternating them in position, as shown in the plan view, the screws on same side of joint being spaced apart three or four inches. Next finish the gunwale with a suitable molding, something like that shown in Figs. 3 and 4. Taking two pieces of proper length—one for either side—plane down the backs of one end of each for a distance of 18 inches, and, beginning about 9 inches back of the point of the stem post, fasten with screws to the outside edges of the sides, and cut off flush with the back of stern.

The shell of the boat being finished, next in order will be bracing and stiffening, and providing it with seats and necessary rowing and steering apparatus. The keel should be pieced out to compensate for the curve in the bottom at the stern. This is done with 1-inch plank, cut out as shown in Fig. 1, and nailed for a good part of the way through to the main keel. It is further kept from twisting off by a brace of ⅞ or 1-inch half-round iron screwed to the stern piece, and into the end of the keel piece for the best part of its depth. The ends of this brace are forged with lugs turning outward, and holes punched through them to catch the rudder hooks. Figs. 1 and 4 show this construction.

For stiffening the bottom and sides, first lay two oak battings, 1 by 1½ inches, across the bottom, about 18 inches fore and aft of the middle. Lay these on their edges, and fasten from under side of bottom with 1½ inch screws. As shown in Figs. 1, 2 and 3, the sides are braced from these by oak knees cut from inch plank fastened from the outside.

Probably the most common and certainly the most dangerous error of amateur boat builders is that of getting the seats too high. Rowing seats should *not be higher* than 6 inches nor broader than 8 inches. For this boat make them of three-quarter stuff, supported at their ends by props resting on the bottom of the boat. Fig. 1 shows these in dotted lines, and they are also represented in Fig. 3. Never nail narrow seats to the sides, or to cleats fastened to the sides, as either of these methods unnecessarily mutilates the shell of the boat, and is sure to bulge the sides and cause a leak. The stern seat may be an inch higher than the rowing seats, as the load upon this seat is supposed to be more stationary. The stern seat may be about 20 inches broad, and a space about 10 inches wide, should be left between it and the stern piece for the reception of sponge, lock, etc.

As shown in the figures, the rowlocks are each rigged out about five inches; they are made of half-inch round iron, in two pieces, the first consisting of the rowlock brace, the ends of which are turned over the gunwale into the inside of the boat, each end being fastened by quarter-inch bolts, two inches apart, passing through the side boards. The ends and top of the brace are flattened, and to the top is riveted the rowlock proper. If swivel rowlocks are preferred, they may of course be dropped into holes in the top of the braces, instead of being riveted. The rowlocks should be placed at about the widest part of the boat, and after they have been put in, the proper position of the rower's seat may be determined, and a second seat put in position for a foot brace or stretcher. Use 8 or 8½ foot oars.

The method of making the rudder and tiller is sufficiently evident from Figs. 1 and 2. Regular rudder hooks may be purchased at a ship chandlery or hardware store. A

much cheaper contrivance is to simply screw two stout screw eyes, one above and the other below the lugs in the end of the keel brace, and for a pivot passing clear through all, a stout and snugly-fitting wire, with one end turned over to keep it from falling through. The rudder is thus enabled to swing freely, and is both supported and prevented from rising as the boat sinks.

All joints should be made in white lead, and all hardware galvanized, if obtainable. If galvanized screws cannot be procured, each one used should be first put into its place, then removed, and, after filling the hole with white lead, again "sent home."

Finish up the stem piece, leaving it from one-quarter to five-sixteenths of an inch wide at the point.

After completion, give the boat two or three coats of raw oil, allowing each a sufficient time to dry before applying the next. For the protection of the stem post and joints at the bow, it is advisable, though not absolutely necessary to cover them with a single piece of pliable galvanized sheet iron, as shown in Fig. 1.

If ordinary care be taken in making the nailed joints, there should be no occasion for caulking after they have had a fair chance to swell shut. If found necessary, however, it should be done with the greatest care, as a caulking tool of any description is apt to draw the nails and make a worse leak than before. Give your boat one *good* coat of *good* paint, and this, together with the oil, will be of more service than a half dozen poor ones.

The following estimate of cost is based upon present New York city prices:

77 feet half-inch white pine, planed both sides	$3.85
4 feet ⅜-inch, for seats, planed one side, and materials for stem and stern pieces	30
32 feet molding	38
Oak batting and knees, sawed out	25
Hardware	1.00
Pair oars, 8 feet	1.50
Forging outrigger, rowlock, stern stay-bolt, and keel brace	1.25
Paint, oil and white lead	1.10
Total	$9.63

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

TO ADVERTISERS.

The YOUNG SCIENTIST has been received with so much favor that its circulation is already greater than that of any other monthly Scientific or Mechanical journal published in the city of New York, with the exception of the *Popular Science Monthly*. It goes into the best families, and has their confidence. NO CLAP-TRAP ADVERTISEMENTS, OR ADVERTISEMENTS OF PATENT MEDICINES RECEIVED AT ANY PRICE.

ADVERTISING RATES—30 cents per line, nonpariel measure.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,
P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers for a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued.

As it is inconvenient to keep book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

The Study of Natural History.

THE study of natural history always has a special fascination for young people. Plants, insects, fishes, birds, all have peculiar charms, and when we come to know their names and something of their habits, they seem to us like familiar acquaintances

when we meet them in our walks. To those who have never made the acquaintance of these outdoor friends, a country walk is like the visit of a stranger to a large city. He knows no one, and although the store windows may attract him by their brilliancy, and the buildings please him by their magnificence, he loses that pleasure which is derived from intercourse with those we know and love. Those who have become familiar with plants and animals find friends and familiar acquaintances on every hand, and during their summer rambles are "never less alone than when alone."

In the study of botany and kindred sciences, it is the first step that is always the most difficult. Young people find it so difficult to make a beginning, especially when no teacher is at hand. We have, therefore, persuaded a well-known teacher of botany to give us a series of articles on "How to Begin the Study of Botany." These articles are not intended to teach *botany*, so much as to show young people how they must go to work to study this science; and it is assumed that those who wish to get the full advantage of these articles will study some simple text-book—such as "Gray's Lessons," "Wood's Text Book," or any other good elementary work. The first article will appear next month.

Exchanges.

WE have been asked to publish our rules in regard to exchanges—the time they are kept in, etc.

The general rules we publish at the head of the exchange columns. As we charge nothing for inserting exchanges, the time that they are kept in must depend upon our own convenience as to space, etc. Sometimes they are kept in for a long, sometimes for a short period. Our desire is to do everything we can for the convenience of our subscribers, but whenever we find occasion to omit the exchange list or any part thereof, we reserve the right to do so.

Of course those who wish to bring any particular subject before our readers with certainty and regularity, can avail themselves of our advertising columns; and notwithstanding our large circulation, we have placed the rates for such advertising so low that they are within the reach of all. Some who are not subscribers but who have seen the journal in libraries, or in the hands of friends, have sent in exchanges. To such we would say that the privileges of our exchange column are open only to those who are regularly entered on our books as subscribers. The amount of advertising that we *give* to our exchangers would cost them many times the subscription to the journal if they obtained it at usual rates. It is not, therefore, asking too much to request would-be exchangers to support the journal by their subscriptions.

Something Out of Nothing.

NOTWITHSTANDING the apparent absurdity of the thing, there is no bait more attractive to fools than the promise of a great deal for a very little, or even of something for nothing, and nowhere have more victims been found than amongst country people, who accept, without doubt, the promises of the man who offers a powder which will produce a pound of butter from milk which contains only an ounce of that article. The trick is an old one, and a very worthless one. The powder consists chiefly of alum and similar salts; these form a combination with the cheesy part of the milk, and change it so that it may be gathered into lumps resembling butter.

Every sample of milk contains just so much butter and no more, and the proportion which these powder sellers claim to attain is always greatly in excess of the amount contained in the very best milk. The product has, somewhat, the appearance of butter, but its flavor is bad, and it does not keep. Those who allow themselves to be deceived by such proposals are very apt to lose both their money and their milk.

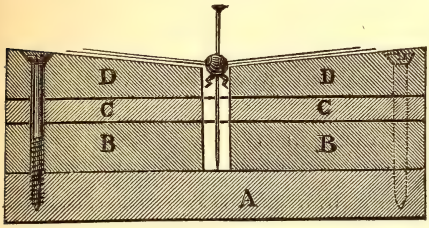
Laboratory & Workshop

Mounting Board for Entomologists.

The season has now opened for entomologists, and as there are, no doubt, among your subscribers, a large number of collectors of insects, I send you a drawing of a mounting board for butterflies and moths, which I have devised for my own use.

The advantages of using a mounting board for Lepidoptera are two-fold. The insects may be arranged in any desired position, and left until rigid, and they will stand at a uniform height on the pins in the cabinet.

The accompanying sketch is an end section, one-half full size, and it is very easily made, as follows: For the bottom, A, use a piece of hard wood, that the pins may only be pushed



MOUNTING BOARD FOR INSECTS.

against and not into it. The parts, B, C and D are made of pine or whitewood (not cedar), each piece being just twice the size represented in the engraving, and about 18 inches long. The top pieces are cut thin on the inside edges to give the wings of the insect a slight angle when set. For small insects and beetles the top pieces are left off, as they are of use only in setting the wings.

It is well to have several boards with the space for the bodies of different widths, as many of the moths have very stout bodies.

Between the pieces B, C and D, are laid thick paper or cardboard, through which, when in use, the pins are passed, and the whole screwed together with slim screws, three or four on a side.

When necessary new paper may be put in. As the pin can not enter the hard wood, the insects are sure to be set at a uniform height.

Any information concerning the killing or preserving of insects will be cheerfully furnished. F. C. SMITH.

Bridgeport, Conn.

Aquaria.

A writer in *Science Gossip* relates his experience with aquaria as follows: "I have kept a great number of aquaria, both salt and fresh water ones. I have often watched the sticklebacks, both salt and fresh water, and both sorts are very fond of attacking other fish, particularly the fresh water species. The latter attacked goldfish, roach, dace, minnows, and other kinds of fish, as well as newts and tritons. They nibble the tails and fins off the fish, particularly the goldfish, and the fish get diseased through it, and pine away and die. I have lost a great many goldfish by their depredations. They nibble or bite the toes and tail off the newts: I have seen their tails bitten so frequently by them that there has been very little left of them. I should never advise any one to place them in a nice-stocked aquarium, and they should be kept out of small ornamental ponds where there are goldfish. If you wish to see how destructive they are, place some of those fish or animals that I have mentioned in an aquarium by themselves; you will then see that the sticklebacks will not let them rest a minute; they will worry the poor fish to death."

A House Fired by a Milk Can.

One of our exchanges quotes the following: "At Aurora, Illinois, a few days ago, a milkman left a milk can turned bottom upwards on a table near his house in such a way that it reflected the rays of the sun on a window after the manner of a burning glass. The blind caught fire from the heat, and, but for the timely discovery of the flames, the house would have been consumed."

And then asks, "Can this be?" Certainly; nothing more simple. The bottom of the can was probably made concave, so as to be strong, and the dairy maid was probably very neat and cleanly, and made it shine as brightly as newly planished metal. Under such circumstances the concave bottom would act like a burning mirror, and if at exactly the right distance from the blinds, would readily set them on fire when the sun shone bright.

Lichen Ornaments.

A lady in Mississippi, writing to the "Household," says: "I have a cross, a wreath and a small basket for the mantel, made of them. Cut the pasteboard the desired shape, and tack the lichens

on, overlapping them so as to conceal the stitches, and varnish. I think bright bits of wool, or small beads, very small leaves, sprigs of moss tacked about in the interstices, improves them, and make them resemble shell-work more. Those who live in the country can easily procure the lichens from old logs, stumps and rails. They should be gathered before very cold weather, as I think they are injured by it."

What will the Weather Be?—The agricultural editor of the New York "Sun" has carefully tested the so-called "Signal Service Barometers," and the following is the result at which he arrives: "The so-called 'storm glasses,' usually made of a solution of gum camphor in pure spirits, are really of no value whatever in indicating the weather in advance. We have one of the best in the market, and, after watching it closely for the past year, have come to the conclusion that it is utterly worthless for the purpose intended."

Inquiries and Answers.

Inquiries.

22. Will you please tell me how to burn iron or platina wire so that it will light gas? **

23. Please publish a recipe for mending common white tableware. I have tried gum shellac, but it does not answer the purpose; it was the only kind of shellac I could obtain, and I tried it according to your directions in your article on cements.
J. G. J.

24. In your April number, you told how to make a lamp out of an ink bottle. Will you tell me what oil to use. I tried it with alcohol, and it burned very well. —

25. What are the chemicals used in preserving flowers? E. VON A.

26. Will some one please tell me how to make cloth waterproof, so that I can use it for a canvas boat, and still be pliable, so I can take it off and roll it up. 000.

27. What is the simplest method of making a cheap electrical machine that will charge a Leyden jar? W.

28. Will some reader give a cheap and easily applied silver-plating fluid? F. L. T.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Wanted, telegraphic and mathematical instruments; Pitman's Phonography in exchange; also thorough instruction in same by mail. F. S. P., King's River, Fresno County, Cal.

Cigar machine to exchange for bracket saw or good microscope. Leonard Alexander, Linneus, Me.

Wanted, microscope, or scientific and mechanical books and apparatus, in exchange for printing press, cost $21, with or without type and material. J. P. Burbank, Salem, Mass.

Wanted, microscope; new Tillotson relay and part cash given in exchange. W. O. F., 83 Downing street, Brooklyn.

To exchange, a Kidder electric battery, for a private line telegraph instrument. Charles L. Feldkamp, 200 W. Randolph street, Chicago, Ills.

Wanted, complete Lester combination scroll saw in good condition; books in exchange. J. T. Jackson, Box 48, Metuchen, N. J.

First-class scroll saw, double treadle, all improvements, worth $40, for second-hand Tolles' objective, not higher than 1-5. John D. White, Chicopee, Mass.

Camera for taking portraits wanted; state what is wanted in exchange. J. F. H., care of this journal.

Wanted, second-hand dictionary, and book on shorthand; state what is wanted in exchange. P. J. Murry, Box 783, Wilkes Barre, Pa.

Wanted, spring motor to run four sewing machines. Barton A. Whitsett, Box 115, Lebanon, Ind.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

A work on painting and wood finishing, value $1.50, to exchange for scroll saw patterns. R. F. Hanscam, North Barnstead, N. H.

A good telegraph instrument, cost $7 50, for a couple of good books on chemistry, electricity, etc. H. B. Kinney, Hamlin, Brown County, Kansas.

A large number of minerals and fossils for exchange. Persons wishing to exchange please send list to W. H. Hughes, 47 Jeff. Avenue, Grand Rapids, Mich.

Wanted in exchange for a second-hand scroll saw, treadle power and wooden frame, a good Excelsior microscope, or live box. Jos. G. Thorp, 54 West Seventeenth street, New York.

A set of chemicals and apparatus; also a set of wood engraver's tools, glass and instruction book, to exchange for a scroll saw and a microscope. The chemicals and tools cost nearly $40; will give a good trade. F. H. Jackson, Angelica, N. Y.

To exchange, a Pope's air pistol for a set of carving tools. L. Y. R. G., Box 317, Brookfield, Mass.

Wanted, a small turning lathe in exchange for a pair of telephones. J. C., care YOUNG SCIENTIST.

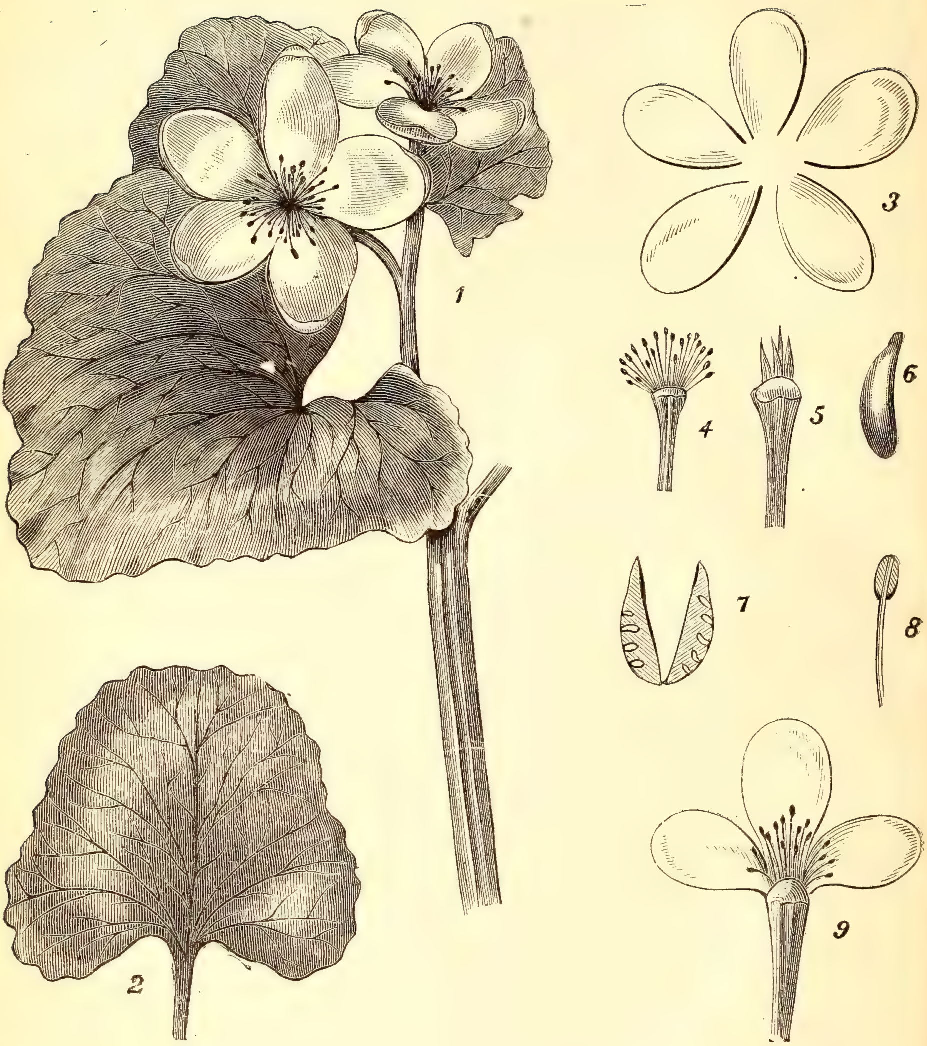
Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Thorough and practical instruction in shorthand will be given in exchange for a microscope, with or without accessories, worth from $5 to $10. Address T. P. Wendover, 68 Christopher street, New York.

Wanted, a small turning lathe, about 1½ inch swing, and 12-inch bed; must be well made; books and apparatus in exchange. R. M., care of this journal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.



HOW TO STUDY BOTANY.

1. Caltha Palustris. 2. Single leaf of do. 3. Calyx of do. 4. Stamens of do. 5. Pistils of do. 6. Pistil. 7. Section of Pistil. 8. Stamen. 9. Vertical Section of the flower.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A Popular Record of Scientific Experiments, Inventions and Progress

VOL. I. NEW YORK, JULY, 1878. No. 7.

How to Begin the Study of Botany.

ON a pleasant day in Spring, I gathered my pupils together; dressed to defy any possible dampness, our feet protected with india-rubbers, that no marshy land might deter us from examining its plants, and laden with our botanical boxes, we started for a ramble in the fields. One enviable boy exhibited a pair of rubber boots, the penalty for which was commissions from his companions to get for them any flowers which might grow in water beyond their reach, all of which he very pleasantly accepted.

Let me describe my class; it numbered six pupils. Hal, the eldest, a bright boy of fourteen, and the owner of the boots; then Lucy, Amy, Ned, Mary and Charlie, who, being our youngest, eight years old, was put under the special care of Hal, by whom he was regarded quite paternally. The children were full of interest for their new study, and in their eagerness would sometimes speak together, so that I was obliged to remind them that I could neither hear nor answer all at once.

Hal walked with me, and the little procession followed, sometimes walking quietly, like grown people, and then one, espying some flower, would dash off, and the others after him. When they had again assumed a quiet demeanor, after one of these sorties, I called their attention to the trees which surrounded us, and bade them notice their different shapes. Approaching an elm, they first noticed its plume-like appearance, and on a nearer approach, observed that the boughs, which, springing from nearly the same point on the trunk, sometimes near the ground, diverged gradually and equally till the normal height of the tree was attained, and, becoming slender, bent downwards in graceful curves, and the branches and branchlets followed this arched arrangement. They passed a group of oaks, and, singling out an individual tree, contrasted its crooked, lon

outstretched arms, and its massiveness, with the curving grace of the elm. Lucy noticed there were dry leaves on it. "These," said I, "are the leaves of last season, and have remained all winter, so we call them persistent; but they will soon be replaced by fresh ones. The beech also has persistent leaves. Pines and firs keep their leaves, but these are called evergreen, because they do not change their color."

Here Amy, who had drawn near, observed that she had seen the ground beneath pines strewn with their sweet brown needles, and asked when pines had new leaves. I answered that the leaves of pines remained for two or more years, but that the fall of their old leaves and the growth of new ones were gradual, so that the tree was never bare.

"See that crooked stem," said Charlie, "it has twined about that bush by its side. What is it?"

"That," I answered, "is a grapevine, and in tropical countries, vines of various kinds become so thick and strong, they form an almost impenetrable tangle in the forests."

We were now approaching the brook, which, swollen by the recent rains, loudly murmured in its stony bed.

"Hal! Hal!" from many voices, "there are some beautiful yellow flowers in the brook. Please get them for us?"

Hal bravely stepped in, and brought back a cluster of March marigolds, fresh and glistening, from the water. The children crowded about me, to hear what I could tell them about the flowers, but I proposed that they should ramble about, and get what other flowers they could, and then we would find some dry seats under the oaks, and examine our treasures. This we did, and presently, with well-filled boxes, gathered under one of the venerable oaks.

"Let us look first at the marigold," (Fig. 1) said I, and taking up a specimen, and bidding each to take one, we began to examine it. "The botanical name of your flower is *Caltha palustris;* look now at the whole plant, as you did before at the tree; it has, like every other plant, its own individual look, and that we call the *facies* of the plant. Look at it more closely; it has a stiff, round stem, furrowed, bearing two or three leaves, and one to three smaller stems, each terminated by a flower; the leaf has a broad rounded form, (Fig. 2) or is kidney shaped; it is a simple leaf, with the margin beautifully scolloped. The lower leaves are on short stems—petioles—but the upper one has a very short petiole, and is almost sessile, which word means to be directly inserted upon the receptacle."

Here Amy, who had been turning the flower about in her fingers, exclaimed, "Why, where is the calyx?"

"What makes you think there is no calyx?" said I.

"I thought the calyx was always green," answered she, "but these petals are yellow."

"Sometimes," I answered, "the calyx is delicate and beautifully colored, like a corolla. This is the case with the *Caltha;* its golden cup is made up of sepals, of which there are five (Fig. 3), and there are no petals; the sepals are parts of the calyx, and the petals parts of the corolla. Remove the sepals, and you will see many stamens (Fig. 4), and these plucked off, you will see in their midst several pistils." (Fig. 5).

Here, with the point of my knife, I cut out a stamen (Fig. 8) and pistil (Fig. 6) from the flower cup, and, placing my magnifying glass before them, exhibited them to the children. Again using my knife, I cut a pistil through vertically (Fig. 7), that its internal structure might be seen. Having passed it about the circle of children, I explained that these little bodies which they saw within it were ovules which would ripen into seeds; the part of the pistil which contained them was called the ovary, and its cavity a cell. This ovary was one-celled.

"Do you think of any flower this *Caltha* resembles?" I inquired.

"Yes," spoke up Mary, "it looks like a buttercup."

"It belongs," said I, "to the same family, and the flowers of this family, though showing great diversity of form, are united

by this characteristic; all their parts are separate, and on the receptacle."

Here, taking a flower, I pulled off its different parts, sepals, stamens and pistils, and showed the children that they were entirely distinct and unconnected with each other, and cutting through a flower vertically (Fig. 9), they noticed that all the parts were on the receptacle, which I now told them was the top of the flower stalk or peduncle.

"Let us look at the other flowers you have."

The boxes were opened, and their collections comprised dog-toothed violets, wood violets, columbines, saxifrage, antennaria (which the children called pussies), houstonia, anemones, and a flower about which a dispute arose, some saying it was an anemone, but others, observing a difference, said it was not an anemone. Charlie had gathered chickweed, on which the others looked scornfully, it was so small and common, they said. Observing the little fellow's face fall, I told him he was quite right to pick it, for no matter how small or common a flower was, it was just as good to examine as a larger or rarer flower. Thus encouraged, he brightened up, and produced some dandelions.

"Let us," said I, "now collect our flowers and return home. To-morrow we will meet at my house, and examine them."

This was done, and my little party turned homewards, tired but happy.

To be continued.

How to Study Entomology.

BY F. C. SMITH.

II.

Continued from page 75.

AS many of the rare moths fly only by night, the collector who will take his lantern and search the fields, and especially the woods, will be amply rewarded by finding specimens that are seldom seen by daylight.

Sugaring.—Moths are attracted by sweets and dazzled by bright lights. We may form artificial feeding grounds for them by smearing trees, fences, stumps, stones, etc., with a mixture of sugar, treacle, or coarse molasses, and beer. Equal weights of treacle and the cheapest brown sugar, boiled to the consistency of very thick molasses, will make a good preparation for sugaring. Just before using, a very little rum may be added, to intoxicate specimens that may come to feed.

The ground should be chosen beforehand, and toward nightfall, the places selected smeared with the preparation. It is not necessary to use a large quantity, a little brushed on with an old brush or rag being sufficient. The locality selected may be in an open field, but the edge of a piece of woods is preferable. Several places may be worked at the same time, each being visited in rotation. A bulls-eye is more convenient and effective than an ordinary lantern. If a common lantern is used, a reflector should be placed behind the light to intensify it as much as possible. A bulls-eye, being smaller, may be attached to the waist by a band or strap, throwing the light forward and yourself in the dark. The net, ether, and collecting box, described last month, should be taken, and the insects captured in the ordinary manner.

Should the collector possess unusual luck, and not wish to be hindered by pinning the

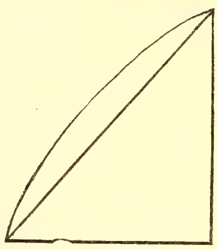


Fig. 1.

specimens as they are captured, it will be found very convenient to have some small paper pockets made by cutting off the corners of old envelopes in the shape shown in the engraving.

The same resorts may be worked through the season, as they will soon become the

popular and favorite meeting places of valuable specimens.

Trap for Moths.—An old tea chest or grocer's box forms the basis of a good trap. By reference to the figure the construction

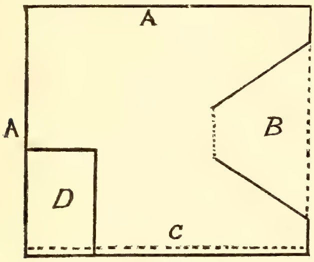

Fig. 2.

is easily understood, and it may be made by any boy. The box, A A, has a circular hole cut in one side, and a coarse canvas or wire gauze funnel fastened in at B. The bottom may be covered with the sugar and treacle described above, and this covered with gauze or canvas, C. A small door at D, with leather hinges, and fastened with a button, will be convenient for taking out specimens. This trap, when set in a field at night, will often contain next morning a large number of beauties.

Sweeping.—For securing a variety of small moths, flies, beetles, etc., the process called sweeping is very successful. The net is here used by walking through a field of grass or stubble, and constantly sweeping it back and forth in a half circle ahead of the collector, the net just clearing the ground. An infinite variety of insects will be obtained by this method, out of which select those cared for, and confine in small pill boxes or envelope corners.

Setting Small Insects.—Insects that are too small or too delicate to be pinned, are easily mounted on cardboard or very stiff white paper. A sheet of cardboard may be covered with specimens, and when full cut into squares, each square containing an insect. Thick gum arabic water, with a very little corrosive sublimate (poison) added, makes a good gum for fastening the specimens to the cardboard. A spot about the size of the insect should be gummed, the specimen placed on this, the legs adjusted and then allowed to dry.

Remember to keep the record of all collections, with date, locality, number, etc.

Larva.—The collector will often find worms, grubs and caterpillars; these are the larvæ of future moths and butterflies, and should be saved, especially those that are found feeding. A few of the leaves they are feeding upon should be taken, with which to feed them until they spin. The large green worms found on fennel, tobacco, parsley, carrot tops, elm and mulberry trees, are valuable, and much amusement and instruction will be derived by watching them during their transformations. They may be put in paper boxes, with their food, and most of them will spin, though some species will bury themselves in the ground, and enter the pupa state without forming a cocoon. For this reason it is advisable to put a little earth in each of the boxes, and when the larva is inclined to dig, transfer it to a jar or tin fruit can nearly filled with earth. All larvæ should be kept in a warm place, which will hasten their transformations.

To be continued.

Simple Lessons in the Art of Photography.

COLLODION.

COLLODION is a solution of gun-cotton in sulphuric ether and alcohol. Cotton consists chemically of carbon, hydrogen and oxygen; gun-cotton contains an additional element, namely, nitrogen, which renders it explosive. Photographic gun-cotton, that is, the gun-cotton used in photography, is not so explosive as gun-cotton used for military purposes, but it is perfectly soluble in a mixture of ether and alcohol. The technical name for gun-cotton in photography is *Pyroxyline.*

Cotton or filtering paper is transformed into pyroxyline by immersion into a mixture of nitric and sulphuric acid. Only the finest cotton or the best Swedish filtering

paper should be used. It is first freed from all resinous and fatty matter by boiling it in a two per cent solution of carbonate of potassa for a few hours. The cotton is then taken out, washed in several clean waters, and finally left to soak in clean water for twenty hours. All superfluous water is pressed out, and the cotton is dried either by artificial heat or in the sun.

Any vessel of glass or porcelain, large enough for the quantity of gun-cotton to be prepared, can be used. For half an ounce of cotton take 12 ounces commercial sulphuric acid, which is first poured into the vessel; next add gradually, constantly stirring with a glass rod, three ounces water, and finally pour in four ounces commercial nitric acid. The mixture is well stirred before the cotton is introduced in small portions, and left in the acid for from eight to ten minutes. The cotton is moved about in the fluid with a glass rod to prevent unequal action of the acid. The acids should, by means of a water bath, be kept at a temperature of 150° Fahrenheit. At the expiration of the prescribed time the cotton is removed, with glass rods, out of the acid, and then washed in several clean waters, till it shows no acid reaction on litmus paper. It can be dried by hot air below 120°, and has to be preserved in an air-tight box, well protected against light and moisture. Cotton is thus transformed into pyroxyline, filtering paper into papyroxyline.

The best solvents of pyroxyline are sulphuric ether and alcohol, generally taken in equal proportions. The ether should be chemically pure, and the alcohol at least 95 per cent. A want of ether in the collodion sometimes causes the film to peel from the glass after it has been taken from the silver bath. Excess of ether will sometimes result in a species of unevenness called curtains. When the collodion contains too much alcohol, the fact is sometimes betrayed by its containing "nobs," that is, small lumps of undissolved collodion. Poor alcohol will produce crossnetting in the film, namely, a kind of network extending over the whole surface. A little ether added to the collodion sometimes cures the evil. Such plain collodion is sensitized by the iodides and bromides of different metals. Iodides produce vigor and brilliancy in the negative, while bromides soften and harmonize great contrasts, and show greater sensitiveness for middle tints. In the preparation of collodion for special purposes, these characteristics of the sensitizer should decide the selection of the formula.

The iodides of cadmium glutinize collodion, whereas an alkaline iodide liquefies it. The iodides and bromides most generally employed are those of lithium, potassium, sodium, ammonium and cadmium.

We here give some of the best formulæ for bromo-iodized collodion:

1. For Negatives—Alcohol, 95 per cent, 4 ounces; ether, concentrated, 4 ounces; iodide ammonium, 16 grains; iodide cadmium, 8 grains; bromide cadmium, 16 grains; pyroxyline, 48 grains.

2. For Positives—Alcohol, 4 ounces; ether, 4 ounces; pyroxyline, 32 grains; iodide ammonium, 24 grains; bromide cadmium, 16 grains; 4 drops of tincture of iodine.

The preparation of bromo-iodized collodion is conducted in the following manner: Measure off the alcohol and dissolve in it the iodides and bromides, and let this solution stand at least one hour, the longer the better. Add now the cotton in small flocks, and finally pour in the ether. The bottle containing all the ingredients should now be thoroughly shaken, and is then set aside for two or more days to ripen and settle. The clear portion can be decanted into another clean bottle, and is ready for use. If a test with litmus paper should prove the collodion to be alkaline, a few drops of the tincture of iodine can be added.

The bromo-iodized collodion is preserved in full bottles, well corked, in a dark place and cool temperature. It will keep for about a year. Collodion prepared by the above formulæ will ripen in one or two days, and keep eight or twelve months. Collodion prepared only with cadmium can

be considered stable, but its ripening process will extend over weeks instead of days. Exposing the freshly prepared collodion to the sun shortens the ripening process, without detriment to its other qualities.

For pouring bottles, use bottles with projecting lips, and cover the cork and neck of the bottle with a cap, either of glass or varnished pasteboard.

How to Study Science.

THE method of study is also important, and just here is where many otherwise good institutions fail. Every student of nature should meet nature at first hand, and learn to observe her phenomena for himself. Lectures and text books are but minor accessories to study; in the sciences they play a wholly subordinate part; in the laboratory, the field, and the museum, the chief work is to be done. No matter what branch of science is to be pursued, the student from the very first must meet it face to face. The biological sciences ought to be studied in the field, collecting; in the museum, classifying; in the laboratory, with the microscope and the scalpel. Far too often is the study of natural history degraded into a mere memorizing of classifications; as if the transitory part of science were more valuable than the permanent. The student must see, handle, dissect, and investigate for himself. He is to study the phenomena of life, and not merely the external appearance of a lot of stuffed specimens. Chemistry, and physics also, are to be studied chiefly in the laboratory. It is not enough for a student to see experiments, he must himself perform them. Thus only can he learn the true scope of these great sciences. By a proper drill in qualitative analysis, he learns to observe closely, and to reason from his facts to their interpretation. Quantitative analysis gives him accuracy of manipulation, and an insight into the absolute value of experiment. This insight also results from delicate practice with instruments of precision in physics; a kind of exercise of the very highest educational value. If the course of study in any science can be capped by an original research leading to the discovery of new facts, so much the better. In a German university the candidate for a doctoral degree in science is absolutely required to carry out such research, and to submit a dissertation upon it. This is not a severe requirement—every student who has been decently trained is able to come up to it, all the popular notions about the mysteriousness of scientific research to the contrary notwithstanding. Why should we not aim to equal the German standard?—*Popular Science Monthly.*

Microscopy.

How to Make an Aquarium of Microscopic Objects.

TAKE with you a small tin pail down to the seaside, and fill it full of pure salt water. Walk along on the sunny side of some creek or inlet, until you come to a spot where eel-grass or sea-weed is growing luxuriantly. Place your pail of water down beside you, and in it wash carefully a quantity of the eel-grass or sea-weed. Repeat this operation several times at different places, being careful not to soil the water with mud. Now put into your pail a pebble with a choice bit of sea-weed attached to it, and you have all the material necessary for your aquarium. Take it home, and pour the water into a small glass phial, drop carefully into it the stone with the seaseed growing upon it; then, after covering the mouth of the bottle with muslin to exclude dust, place it in a sunny window, and in a few weeks you will be astonished at the result. The sea-weed will have shot out little delicate branches through the water, which will remain perfectly pure and transparent for months, while every drop of it will contain many living objects of different varieties that will increase and multiply to a wonderful extent, and will be ready at all times to be admired under the microscope.

As the water in the phial evaporates, it

will be necessary to add fresh to it. By adding salt water, it is evident the whole would soon become too salt to sustain life.

S.

The Hydra.

THIS fresh water polype is not exactly a microscopic or a very minute object. It is plainly visible to the naked eye when extended, and its beauty will amply pay an examination. Hydras may be found attached to leaves or sticks, during warm weather, in almost any pond. In the aquarium they attach themselves to the side turned towards the light, or to *Anacharis alsinastrum* and to the *Valisneria spiralis.* The hydra can assume a variety of forms; it may appear vermiform (or like a worm), it may attenuate its body and its tentacles so much as to become almost invisible, or it may contract suddenly and show only as a speck of jelly. The tentacles are prehensile organs round a central cavity, and are also used for locomotion. These thread-like organs wind themselves round their prey like a lasso, and completely paralyze it. By gradual curving, the object is brought to the mouth and engulphed there, while any refuse or any undigested parts are rejected from the same opening. Like all the polypes and other low organizations, hydras can rapidly reproduce any part of their body; they may be cut into pieces or divided into halves, and each piece will go on performing the functions of the animal, and will be complete again in a very few hours. One hydra may swallow another without injury to either, or it may be turned inside out without any detriment to its vital functions. Their usual size, when full grown, is about three-quarters of an inch, and the red hydra (*hydra rubra*) is more easily seen in an aquarium than the other kinds. These singular beings are very voracious. They can swallow a worm, a cypris, or a cyclops, of twice their own size. Hydras multiply very rapidly; a portion of their body swells or buds out. and a young one presently appears, remains attached to the mother for several days, when it floats off; or they throw out eggs at one time, and living young ones at another. Hydras appear to be long lived; I have a hydra in my aquarium which I collected ten years ago near Greenwood. *

The Aquarium.

THE secret of success in Aquarium management is to sustain the proper balance between animal and vegetable life, thereby securing purity of the water without change, with consequent life and health to the inhabitants; the aquarium must in fact be a miniature pond. Oxygen is animal life, this plants give off. Carbonic acid is death to animals, this plants absorb—but plants need sunlight to perform their office to perfection.

Eighty-eight years ago, Sir John Dalyell began aquarium keeping. Three times a week his servants trudged two miles to the sea-shore to fill a four-gallon jar with sea water. Sixty-one years this routine was kept up. His specimens were of the orders lower than fishes, his receptacles cylindrical jars holding one animal each. The water was changed daily—oftener if the slightest sediment was to be seen.

In 1842, the first true aquarium principles were recorded. Dr. Ward, recognizing the mutual dependence of the animal and vegetable kingdoms, arranged them together in water. Mrs. Annie Thynne followed with the same ideas some four years later.

The marine aquarium presents attractions the fresh water cannot afford—but the fresh water affords attractions sufficient to interest the novice. The care of the latter is less. In case of accident it can be sooner renewed or replaced. It is easier to begin with and is more easily kept in order. The fresh water should precede the marine aquarium.

The brooks, creeks and ponds will afford the furnishing, whether of animal or vegetable life, and the study of the life beneath the waters, if one may obtain their own specimens, will add new interest to it all. The aquarium to the young will afford lessons that cannot be gained from books; lessons upon Nature's immutable laws. Artificial law may often be evaded with impunity, but natural laws never. The penalty inevitably follows, and that penalty is oftenest death. The study of the aquarium will favor the development of thought and inquiry, and the observations will become almost personal experience.—*Ex.*

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers for a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued.

As it is inconvenient to keep book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

Contributions for the Young Scientist.

WE have been offered lately, by title, quite a large number of articles for this journal, many of which, if as good as their authors think they could make them, would be quite acceptable to our readers. Others, however, are of such a character as would not tend to advance the aims we have in view. To save trouble and unnecessary correspondence, we would say to those who think that they can furnish something of interest to our readers, that the only way to obtain a decision is to send on the articles themselves.

It is much more easy to say what we do *not* want than to describe an acceptable article. We do not want mere literary articles; even historical articles are out of place. All essays on the beauties and value of science go at once to the waste basket. What we want is *practical* articles, telling how to *do* something. If you have made some useful article by a new method, or of new materials; if you have devised some new process or wrinkle, or some new way of doing an old one, send us an account of it, and it will no doubt be acceptable. But we must see it before we can decide, and to receive our attention at all, the article must be thoroughly practical.

To Our Exchangers.

VERY many of our exchangers seem to overlook the conditions upon which exchanges are inserted. As the space now occupied is nearly as much as we can afford, we have determined hereafter to limit the exchange department to a column and a half; new exchanges will be placed at the beginning, and the old ones will be dropped as fast as they are crowded off at the other end. All exchanges will be limited to thirty words, and all attempts at buying and selling will be rigorously excluded.

Fourth of July Pistols.

THE love of firearms which exists in the minds of most boys is undoubtedly an inherited remnant of that instinct which leads most savage races to be hunters. Almost every boy is born a hunter. Set a wild animal, such as a rabbit or a woodchuck, before a crowd of school boys, and see how they will go for it! This instinct leads the boy to clamor for a gun or a pistol as soon as he has donned his first pair of pants. Unfortunately his request is gener-

ally refused, until the universal noise-making of the Fourth of July comes to reinforce his demands, and notwithstanding all that has been said or written about the dangers of pistols or cannons, every Fourth brings an enormous number of serious and fatal accidents.

Now, if instead of endeavoring to *stifle* the fondness for firearms, parents and guardians would endeavor to *guide* the taste of boys in this direction, it would be much more sensible. The boy who is in the habit of using firearms for sport or for marksmanship will never degrade them to the mere purpose of making a noise. By most persons, however, the most dangerous and foolish course is in general pursued toward the lad who shows an inclination to use the gun, particularly if his guardian be not himself a sportsman. When a boy first asks permission to use a gun, it will be found that most old women (whether they wear petticoats or not) forbid the use of what they consider such a dangerous weapon, but are willing that he should have a *pistol*,—which is a far more dangerous plaything, both for the boy himself and for those who are about him. The long barrel of a gun is not readily pointed either in the direction of ourselves or others, without our knowing it; while the shorter pistol frequently comes into dangerous range either of the person who holds it or of others, without being immediately perceived. Moreover, a boy in such circumstances receives no proper instruction in the handling, loading, carrying, and discharging of a gun, when by his own stealth or the carelessness of his guardians, he comes into possession of one. Those rules, which, from long habit, have become second nature to all good sportsmen, are unknown to him, and of course unacted upon. He carries his gun with the hammers on the caps, and with the muzzle pointing downward or horizontally toward every point of the compass. He pokes the muzzle through any fence he may have to cross, gets through or over himself as best he can, and then drags the gun after him, frequently receiving the contents of one of the barrels while so doing. In short, his gun, instead of being an instrument of honest recreation, becomes the source of stolen sprees, and is sooner or later a cause of serious accident. Sensible guardians ought to abandon all this. If a young man shows an inclination for the sports of the field, let them see that he is provided with a safe and efficient weapon, and carefully instructed in its use. Youth must have recreation, and it is better for a young man that he should devote his days to the green fields than his nights to the green table.

Laboratory & Workshop

New Photographic Process for Copying Drawings.

The following is a convenient method for reproducing drawings, plans, maps, and line engravings in general. The paper is first prepared by dipping it in a bath composed as follows: Distilled water, 10 ounces; perchloride of iron, 1 ounce; oxalic acid, 4 drachms.

When dry, the paper, if protected from light, can be kept as long as may be necessary. To copy a drawing, the model, on oiled or transparent paper, is applied on some paper thus prepared, and the whole exposed to light in an ordinary photographic printing press. In summer and in the sunlight, an exposure of from fifteen to thirty seconds is sufficient; in winter, forty to seventy seconds; in the shade, during clear weather, from two to six minutes; and, lastly, when the weather is overcast, cloudy, rainy or snowy, from fifteen to forty minutes are necessary.

The paper, on being withdrawn from the press, is placed in a bath containing from fifteen to eighteen per cent of ferrocyanide of potassium. It is then washed in an abundance of water, passed in a bath containing eight or ten per cent of muriatic acid, washed again, and dried.

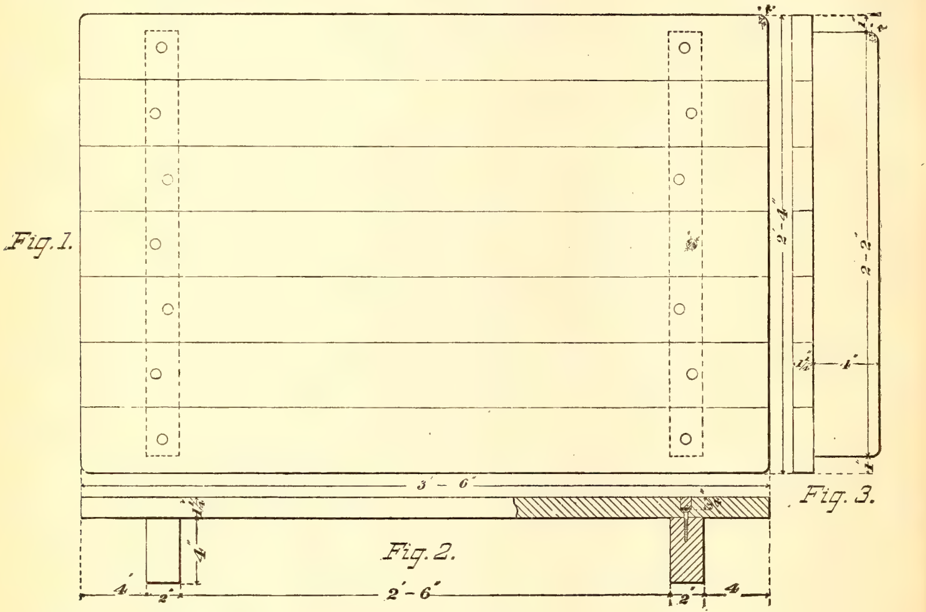
The explanation of the operation is as follows: The perchloride of iron, under the influence of light, is reduced by oxalic acid to the state of protochloride, which is soluble in a solution of ferrocyanide of potassium, while

the same potassium salt transforms the perchloride into the insoluble cyanide, well known under the name of Prussian blue. As the black lines of the engraving to be reproduced protect the prepared paper from the action of the sun, the perchloride remains unchanged in such places, and the drawing appears in the copy in sharp lines of a dark blue color on a white ground. The advantage of the process is that a positive picture is obtained immediately.

How to Make a Drawing Board that will not Warp.

The two sizes of drawing paper most commonly used by engineers and architects are "Double Elephant" and "Imperial." These are the most convenient sizes, and drawing boards made to suit them admit of the use of other and smaller sheets of paper. A drawing board large enough to take "Double Elephant" paper, which in size is 40 by 26 inches, should be 42 by 28 inches, and this will allow the use of all sheets of drawing paper of sizes within these dimensions, as "Atlas," "Columbier," "Elephant," "Imperial," "Super Royal," "Royal," "Medium," and "Demy."

A great many of the drawing boards kept for sale amongst artist's materials are made without reference to the sizes of drawing paper or their suitability for the T square. Most draughtsmen prefer to have drawing boards made of proper dimensions, and in a way that will keep them from warping. The following is a very excellent plan for the construction of a drawing board. The dimensions are given for a size to suit "Double Elephant" paper. It will be observed by the accompanying drawing that the board is made in seven pieces, each 4 inches wide and 1¼ inches thick, jointed together by square joints with glue only, but without tongueing and grooving. On the back are two strong cleats, 4 by 2 inches, set on edge near the ends of the board, and secured by screws from the face of the board, the heads of which must be sunk deep enough to avoid the points of the drawing pins. The holes made for countersinking the screws must be plugged up with wood glued in, the grain of which should run parallel with that of the board. The manner of doing this is plainly shown by the section, Fig. 2. The four corners of the board and lower corners of the cleats should be slightly rounded, so as to



DRAWING BOARD.

avoid the liability to splinter in handling. The material best adapted for this, and all drawing boards is well seasoned, clear, soft white pine.

It is often convenient to have a drawer attached to the drawing board. This may be attained by putting hard wood battens or runners about 2 inches deep on the inside of the lower edges of the cleats.

The construction of this kind of drawing board will be readily understood by reference to the drawing, and will be found preferable to all others.

Veneering.

The softest woods should be chosen for veneering upon. Hard wood can be veneered—boxwood with ivory, for instance; but wood that will warp and twist, such as cross-grained mahogany, must be avoided.

The veneer, and the wood on which it is to be laid, must both be carefully prepared, the former by taking out all marks of the saw on both sides with a fine toothing plane, the latter with a coarser toothing plane. If the veneer happens to be broken in doing this, it may be repaired at once with a bit of stiff paper glued upon it on the upper side. The veneer should be cut rather larger than the surface to be covered; if much twisted, it may be damped and placed under a board and weight overnight. This saves much trouble; but with veneers that are cheap it is not worth while taking much trouble about refractory pieces. The wood to be veneered must now be sized with thin glue; the ordinary glue-pot will supply this by dipping the brush first into the glue, then into the boiling water in the outer vessel. This size must be allowed to dry before the veneer is laid.

We will suppose now that the veneering process is about to commence. The glue in good condition, and boiling hot, the bench cleared, a basin of hot water with the veneering hammer and a sponge in it, a cloth or two, and everything in such position that one will not interfere with or be in the way of another.

First, damp with hot water that side of the veneer which is not to be glued, then glue the other side. Second, go over, as quickly as possible, the wood itself, previously toothed and sized. Third, bring the veneer rapidly to it, pressing it down with the outspread hands, and taking care that the edges of the veneer overlap a little all round. Fourth, grasp the veneering hammer close to the pane (shaking off the hot water from it) and the handle pointing away from you; wriggle it about, pressing it down stoutly, and squeezing the glue from the centre out at the edges. If it is a large piece of stuff which is to be veneered, the assistance of a hot iron will be wanted to make the glue liquid again after it has set; but don't let it dry the wood underneath it, or it will burn the glue and scorch the veneer, and ruin the work. Fifth, having got out all the glue possible, search the surface for blisters, which will at once be betrayed by the sound they give when tapped with the handle of the hammer; the hot iron (or the inner vessel of the glue-pot itself, which often answers the purpose) must be applied, and the process with the hammer repeated.

When the hammer is not in the hand, it should be in the hot water. The whole may now be sponged over with hot water, and wiped as dry as can be. And observe, throughout the above process, never have any slop and wet about the work that you can avoid. Whenever you use the sponge, squeeze it well first. Damp and heat are wanted, not wet and heat. It is a good thing to have the sponge in the left hand nearly all the time, ready to take up any moisture or squeezed-out glue from the front of the hammer.—*Jour. of Applied Science.*

Clothes-Moths, and How to Get Rid of Them.

Prof. C. V. Riley gives the following very interesting account of the clothes-moth, and indicates the best methods of killing them:

"The name clothes-moths is applied to several distinct but similar species of minute moths belonging to the family *Tineidæ*, which, in their larval state, are very destructive to woollen goods, fur, skins, feathers and similar substances. Among them may be mentioned the clothes-moth (*Tinea vestianella*), the carpet moth (*T. tapetzella*), the fur moth (*T. pellionella*), and the hair moth (*T. crinella*). These Tineidæ have slender bodies, and lanceolate, deeply-fringed wings that expand 6-10ths or 8-10ths of an inch. The antennæ and palpi are short and thread-like, and there is a thick orange or brown tuft on the forehead. The colors range from buff to drab and dark gray. The eggs are laid in May and June (the moth dying immediately afterwards), and hatch out in fifteen days. The young worms at once pro-

ceed to work, gnawing the substances within their reach, and covering themselves with the fragments, which they shape into hollow rolls and line with silk. These rolls are by some carried on their backs as they move along, and by others fastened to the substance they are feeding upon, and they are enlarged from time to time by additions to the open extremities, and by portions let into the sides, which are split open for this purpose. In such ambush the worms carry on their work of destruction through the summer; rest, in seeming torpor, during the winter, and change to chrysalids early in the spring. They transform again in twenty days, and issue from their shelter as winged moths, to fly about in the evening till they have paired and are ready to lay eggs. Then follows an invasion of dark closets, chests, and drawers, edges of carpets, folds of curtains, and hanging garments, and the foundation of a new colony is swiftly laid. The early days of June should herald vigorous and exterminating warfare against these subtle pests. Closets, wardrobes, all receptacles for clothing, should be emptied and laid open, their contents thoroughly exposed to light and air, and well brushed and shaken before being replaced. In old houses much infested with moths, all cracks in floors, wainscots, shelves, or furniture, should be brushed over with spirits of turpentine. Camphor or tobacco should be placed among all garments, furs, plumes, etc., when laid aside for the summer. To secure cloth linings of carriages from the attacks of moths, sponge them on both sides with a solution of corrosive sublimate of mercury in alcohol, made just strong enough not to leave a white mark on a black feather. Moths may be killed by fumigating the article containing them with tobacco or sulphur, or by putting it, if practicable, into an oven heated to about 150° Fah."

Current Notes.

A Large Musical Box.—The Khedive has recently had made for him in Geneva what is said to be the largest musical box ever constructed. The case is of inlaid ebony. The instrument will play 132 tunes; it has eleven cylinders, and is furnished with flute, flute basso, drum, bells, and castanets. Each cylinder is 26 inches long. The box has cost £800.

Cementing Labels to Metal.—For attaching labels to tin and other bright metallic surfaces, first rub the surface with a mixture of muriatic acid and alcohol; then apply the label with a very thin coating of the paste, and it will adhere almost as well as on glass.

Stand for Cut Flowers.—A very pretty effect in the parlor or living room may be made by procuring a number of short vials something over an inch in diameter, or so large that they will stand firmly. In these place single roses, or other double blooms, wlth fern leaves or other pretty foliage below them. They will last thus a week, and be very beautiful.

Cure for Burns.—A solution of bicarbonate of sodium applied to burns, promptly and permanently relieves all pain. A laboratory assistant in Philadelphia having severely burned the inside of the last joint of his thumb, while bending glass tubing, applied the solution of bicarbonate of soda, and not only was the pain allayed, but the thumb could be at once freely used without inconvenience. Bicarbonate of soda is simply the best baking soda.

Another House Fired by a Milk Can.—Mr. Miles T. Frisbie, of Otisco Valley, N. Y., writes us that some years ago, on a hot day, he was somewhat astonished by seeing a smoke in his back kitchen, and tracing it to the wall, he found that the house had been set on fire by a pail with a concave bottom, which was set on a bench about 6 inches from the house. If the family had not been at home, the house would no doubt have been consumed.

Case Hardening.—Mr. F. H. Wenham, who is one of the most skilful scientific mechanics in England, contributes to the "English Mechanic" the following note on this subject: "In the directions generally given for this process, it is stated that the articles should be inclosed in a crucible or iron box filled with bone charcoal and carefully luted with loam. This is by no means necessary. The best practice in case hardening is to be seen in the lockwork and furniture of small arms. I have seen gunsmiths use a sheet-iron tray like a small frying-pan. A layer of fresh bone-dust is spread over the bottom of this, upon which the small finished and polished iron fittings are laid, avoiding actual contact with each other. Another layer of fresh bone-dust is spread over, so as to completely cover the articles. The tray is now filled to the top with burnt bone powder that has been used and exhausted by a previous operation. The tray is kept at a cherry-red heat over an open fire for about half an hour, and then the whole contents are instantly turned out into a vessel of cold water, and the articles will be as hard as possible, with the pretty mottled appearance characteristic of this kind of work. The bones are charred only sufficient to drive off the vapor, and just enable them to be coarsely powdered with a hammer. There is

no advantage in favor of hardness of surface by case-hardening at too high a temperature, as this impairs the quality of the bone by prematurely exhausting it, and driving off some of its combining elements, and great heat is also sure to warp the work. Gun-lock work, if properly done, comes out quite true for fitting in place."

An Instructive Experiment.—To prove that the inner dark portion of an illuminating flame contains combustible gases, the general practice with experimenters is to insert into that part of the flame a glass tube, so inclined that a portion of these gases shall rise into it, and thereupon igniting them at the further extremity of the tube, or leading the contents of the tube by an aspirator into a convenient vessel, when its combustibility can then be directly tested. Mr. Heuman has communicated to the German Chemical Society another method, and a simpler one, of accomplishing the result, which seems worthy of notice.

He recommends taking advantage of the well-known fact that a mixture of about four parts of chlorate of potassa and one part of strontium nitrate, heated to fusion, will burn with a very intense flame in hydrogen or illuminating gas, when once the ignition of the oxygen liberated from this mixture is effected by contact with a flame.

To perform this very pretty experiment, the author states that it is only necessary to fuse a small quantity of the mixture in question in a little spoon at the apex of a luminous gas flame, and then to lower it into the dark portion, when a brilliant combustion will immediately ensue; while, when removed to the luminous portion of the flame, or taken altogether out of it, it is at once extinguished.—*Journal of the Franklin Institute.*

BOOK NOTICES.

Manual of Telegraphy. Designed for beginners. By Prof. J. E. Smith. Thirteenth Edition. New York: L. G. Tillotson & Co., 8 Dey Street.

Telegraphy always has a peculiar charm for young people. Indeed we can think of nothing that will give more amusement than a short telegraph line connecting two families. The cost and labor of putting up such a line is very slight, and the manual named above gives such full and simple directions that any boy can follow them.

The Outlines of Natural Philosophy. For Young Children. By Edwin J. Houston, A. M. Philadelphia: Claxton, Remsen & Haffelfinger.

One of the most difficult tasks that one can undertake is to give such clear and simple explanations of the principles of Natural Philosophy as will be easily understood by children. Most of those who have attempted this task have failed from one of two causes: Either the explanations were erroneous, or they were beyond the comprehension of those to whom they were addressed. It seems to us, after a careful examination, that the author of the work before us has succeeded in avoiding both these errors, and he has consequently produced a book which must prove a great boon to parents who have intelligent children, eager for a knowledge of the material world around them. To such we would cordially recommend the little book on our desk. For the purpose intended it is certainly the best that we know of.

Off on a Comet! A Journey through Planetary Space. (A sequel to "To the Sun.") From the French of Jules Verne. By Edward Roth. With thirty-six full page illustrations. Philadelphia: Claxton, Remsen & Haffelfinger.

We hope none of our readers will treat this book as a certain staid old gentleman treated another of Jules Verne's works. After reading a few pages, he threw it down in disgust, and declared that he could not believe one word of it! However much the story may do violence to our sense of probability, or even of possibility, it is nevertheless undeniable that a great deal of the book is absolutely true. Like all works of art, it brings before us conditions of an unusual character, but of a higher grade than any that are likely to occur under ordinary circumstances. In the present instance we are brought face to face with the great laws of nature, operating under conditions such as no human experience ever realized. Our readers will find in this book not only an interesting story of strange adventures, but a great many new ideas in regard to the mechanism of the heavens. Through the whole there runs a vein of humor and anecdote which greatly relieves the dryness of the scientific discussions.

Inquiries and Answers.

Inquiries.

29. Can you give me a recipe for nickel or silver plating metals, with or without a battery? Will an electro-galvanic battery (shocking machine) serve the purpose of battery in plating wares? I manufactured one of your ten-cent batteries; it works like a charm, and I would like to know some experiments to try with it. J. N. H.

Answers.

30. In as concise a manner as possible, I shall attempt to answer an inquiry which appears in letter 27. The cheapest apparatus for charging a Leyden jar is the following: Place an ordinary iron tea tray on a perfectly dry tumbler; then warm a sheet of paper as hot as possible by passing it several times over a gas light, or by holding to a stove. Lay the paper on a board or other non-conducting surface, and rub it vigorously with a piece of india-rubber. Spread the paper on the waiter, to which the jar should now be applied. If the weather is

favorable for such ezperiments, the operation of warming and rubbing will only have to be repeated once or twice to charge the jar sufficiently. I hope that W. will find this method successful.

W. N. M.

31. In answer to J. F. M., to make skeleton leaves, I give him the following recipe, which he can try. The leaves are to be soaked in water for some time; the solid part will then gradually rot out, and leave only the fibres. These will be of a brown color, and must be bleached by means of a weak solution of chloride of lime (bleaching powder). The leaves must afterwards be carefully washed, so as to free them from the chloride of lime, otherwise they will speedily rot. They should then be dipped into a little gum water, and dried.

J. H.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Graham's Handbook, Synopsis, and 1st and 2d Readers Standard Phonography; tools or advanced scientific books preferred in exchange. E. H. Bidwell, Vineland, N. J.

Complete outfit for stamping key checks, worth $10, in exchange for practical receipt books, or bracket saw with lathe and drill attachment. John Whitty, Jr., Polloksville, N. C.

Woodward's Hospital Microscope wanted in exchange for chemical scales and weights; difference in cash. J. Siler, 1,212 Broadway, St. Louis, Mo.

For exchange, an entire printing outfit, cost $50; state what you have to exchange. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Good $50 job printing press, in perfect order, for a scroll and circular saw, or scroll saw alone; saw must be in good order. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, foot power scroll saw, lathe, or both combined, or good microscope, for minerals, books on plant culture, Art Journal in parts, or cancelled postage and revenue stamps. D. S. Kimball, 48 Exchange Place, New York.

Wanted, small steam engine and boiler of from 1 to 2 horse-power; state what is wanted in exchange. Address Jno. McElvery, Flatbush, L. I.

Wanted, telegraphic and mathematical instruments; Pitman's Phonography in exchange; also thorough instruction in same by mail. F. S. P., King's River, Fresno County, Cal.

A set of chemicals and apparatus; also a set of wood engraver's tools, glass and instruction book, to exchange for a scroll saw and a microscope. The chemicals and tools cost nearly $40; will give a good trade. F. H. Jackson, Angelica, N. Y.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a small turning lathe in exchange for a pair of telephones. J. C., care YOUNG SCIENTIST.

Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Wanted, complete Lester combination scroll saw in good condition; books in exchange. J. T. Jackson, Box 48, Metuchen, N. J.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

Wanted, microscope, or scientific and mechanical books and apparatus, in exchange for printing press, cost $21, with or without type and material. J. P. Burbank, Salem, Mass.

Cigar machine to exchange for bracket saw or good microscope. Leonard Alexander, Linneus, Me.

Wanted, microscope; new Tillotson relay and part cash given in exchange. W. O. F., 83 Downing street, Brooklyn.

To exchange, a Kidder electric battery, for a private line telegraph instrument. Charles L. Feldkamp, 200 W. Randolph street, Chicago, Ills.

First-class scroll saw, double treadle, all improvements, worth $40, for second-hand Tolles' objective, not higher than 1-5. John D. White, Chicopee, Mass.

Camera for taking portraits wanted; state what is wanted in exchange. J. F. H., care of this journal.

Magic lantern, nine slides (two mechanical) in complete order, in exchange for good compound microscope. T. R. Barwood, Flatbush, L. I.

A work on painting and wood finishing, value $1.50, to exchange for scroll saw patterns. R. F. Hanscam, North Barnstead, N. H.

A good telegraph instrument, cost $7 50, for a couple of good books on chemistry, electricity, etc. H. B. Kinney, Hamlin, Brown County, Kansas.

Wanted in exchange for a second-hand scroll saw, treadle power and wooden frame, a good Excelsior microscope, or live box. Jos. G. Thorp, 54 West Seventeenth street, New York.

The Phonograph.—Our readers who reside in or near New York, can now have an opportunity not only of seeing and hearing this marvellous invention, but of listening to a very lucid explanatory lecture, which, by the aid of a series of striking and beautiful experiments, is rendered easy of comprehension, even by children. The exhibition is given every evening at Irving Hall, corner Irving Place and Fifteenth street, and in addition to the Phonograph, and Speaking and Singing Telephones, there are the attractions of exquisite music by Geo. Morgan, Madame Cole, Levy the cornet player, and others. The effect produced by the cornet playing of Levy, and the singing of Madame Cole and Mr. Rose, as reproduced by the phonograph, is marvellous. Amongst other feats, Levy played "God Save the Queen" into the phonograph in *four* octaves, and the instrument accurately reproduced his notes!

Those who wish to enjoy a very delightful entertainment, and to obtain a clear idea of the principles of the phonograph and telephone, cannot do better than visit Irving Hall.

VOL. I. NEW YORK, AUGUST, 1878. No. 8.

How to Make An Herbarium.

A Chapter for Young Collectors.

BY JOHN W. BUCK, B. SC.

As the summer advances doubtless many young lovers of nature will begin again gathering wild-flowers, and bringing them home in nosegays, as they have often done before, to be looked at for an hour or two and then, when withered, thrown away. Some may have tried ere this to dry them, and so to keep a record of their industry and their love for flowers, but may not have succeeded to their own satisfaction for want of a little help or instruction to begin with. It is for such that I intend this paper. To make a herbarium may sound a very imposing task, but such it need not be, for it can be done slowly and gradually—a plant at a time, if need be—and the flowers, when thoroughly dried and mounted, if taken care of, will keep an indefinite time and be a lasting source of enjoyment. Nothing is so conducive to a knowledge of our British wild-flowers as to make as complete a collection as possible of them; although those who take my advice and make the attempt will probably be surprised to find how few flowers they already know, and how many there are hidden away under the hedges or in the woods which they never saw before. An object such as this gives a new zest to our country walks, besides making us find out new ones; gives us pleasant associations with particular spots as being the places where we first found such and such a new flower, fern, or moss; and above all gives us new and brightened views of nature and of nature's God.

To collect flowers for an herbarium, all that is necessary is a tin box and a trowel, though some collectors prefer to carry a portfolio containing porous paper and to put the plant under pressure on the spot. This has the advantage of securing it, so that the flower shall lose none of its freshness while being carried home; but it is a cumbrous and troublesome plan, and it will probably

be found, in the case of most flowers, that if they are brought home in a biscuit-tin, and the roots perhaps placed in water to freshen them up if necessary before pressing, that they will appear as good as need be. It will nevertheless be found very convenient to carry a small pocket-book with some porous-paper leaves, in which to preserve at once some blossoms which will require it. For instance, it will be found impossible to bring home an entire dandelion or bindweed without the blossom closing up; and the corolla of the Germander Speedwell, the bright little blue flower often called bird's-eye or cat's-eye, that looks so pretty and lasts so long in the summer hedgerows, will almost certainly be knocked off before the plant can be pressed at home. In such cases these parts must be put under pressure separately from the rest of the plant, and at once. Indeed, such a sleepy plant as the tragopogon, or John-go-to-bed-at-noon, almost requires to be caught with guile. Go in the morning when it is open and press the blossom in the porous paper-book before detaching it from the stalk. Some entire plants, from their delicate and brittle nature, had better be pressed on the spot; as, for instance, the pale green moschatel, the stalks of which are almost sure to snap with the slightest rough usage. Of course, when the roots have to be cleared from much earth, especially if the earth is of a clayey nature, it is absolutely necessary to bring the plant home before doing anything with it. On the whole, the tin box will be found preferable to the portfolio, and the occasions on which the latter must be used will soon be learnt by experience. Better than either, because more convenient, is the regulation vasculum, of japanned tin.

For digging up the plants, since in most cases the roots must be preserved, a trowel is generally recommended. After a few of these have been broken by rough usage in stiff soils, or spoilt by friends who have borrowed them "just for once," they will probably be replaced by a small three pronged fork, about the same size as the trowel, but much more durable. Even this, however, has its disadvantage, which will be found out on trial. In selecting the specimens for preservation, a little discrimination should be exercised. It is best, perhaps, to take two plants of the same kind and dry both, and afterwards choose the best of the two for mounting. It is not advisable to take more, unless they are somewhat inaccessible, or unless, for other reasons, it should be difficult afterwards to obtain more if required, as a large number only fills up the box, takes up a great deal of room in the press, and gives much unnecessary trouble in many ways. Choose, therefore, two plants which are fairly developed, and which show if possible, specimens of all the kinds of leaves the plant may possess, which have some blossoms fully open and others in bud, and, in short, which are in all respects good specimens of their kind. In some cases the leaves are not up when the flower is open, as with the yellow coltsfoot, which flowers in the early spring, but whose leaves are not to be found until much later. It is a mistake to choose too large a plant, under the impression that it will look well; a medium should be aimed at in this matter, as in everything else. Perhaps it is not unnecessary to say that rare plants ought not to be exterminated. Persons who go about hunting for rarities, and who take all they can lay their hands on, are collectors *only*, not botanists. Many of our uncommon ferns are daily becoming rarer, and harder to be found by those who really want to study them, because they are so diligently sought after and dug up by collectors who only want them to sell. My advice is, if you find a rarity, take of it in moderation, and then, in the interests of science, keep your own counsel as to its whereabouts.

In removing a plant, care must be taken not to spoil the root, nor to injure the leaves that spring from near the ground. It is often of great importance that these latter should be kept intact, as they frequently differ from the leaves which grow higher up the stem, and are very useful in

assisting to determine the name of the species. With many plants, as is the case with the coltsfoot, the root will be almost sure to break off sooner or later. Again, a complete blue-bell, bulb and all entire, will be a very good certificate of perseverance for its possessor. The adhering earth should be shaken off as far as possible without doing injury to the roots, and the rest carefully pulled off at home, or removed by holding the root (only) under a stream of water.

The next thing ought to be to name the specimen; and if I could take for granted a little knowledge of botany on the part of my readers, it would not be very difficult to show in brief the easiest method of arriving at the correct botanical and popular names of most of our common wild flowers. For those, however, who know nothing of botany, the best way is to compare the flowers brought home with the illustrations in some such work as Ann Pratt's "Wild Flowers," or John's "Flowers of the Field," or Sowerby's "English Botany," or to obtain the help of some botanical friend. At all events, you need not despair of making good progress with your herbarium, even if you do not know the names of all the plants it contains, as these can generally be added afterwards.

In any case, proceed to dry your plants before they lose their freshness. This is accomplished by pressing them between porous paper. The best paper for the purpose is, or used to be, made by Messrs. Spicer, of New Bridge street, Blackfriars (who also supply white paper for mounting, in sheets about 17 in. by 11 in.), but in default of this, thick blotting paper is said to answer, though I have not tried it. The plants must not be damp when they are put in the press, and if the roots have been washed to clean them, they should be wiped as dry as possible. If for any reason the plants are at all damp, the papers should be changed very frequently at first, even twice a day, until the excess of moisture has been removed. I am frequently asked, "How is it you manage to keep the colors of your flowers so well?" Mainly by attention to this point—by not allowing the flowers to remain damp. Otherwise they are very apt to change their color; as, for example, the wood anemone, or windflower, which generally turns brown, but which may be kept white with proper care. Heath and firs are said to require a dip in boiling water before drying, in order to prevent the foliage from falling off. The same process prevents succulents, such as the curious flesh colored parasitic toothwort, from growing during or after pressure, by killing them at once. Here, also, the superfluous moisture should be removed by a handkerchief before pressing. Do not mix fresh specimens with dry ones, but separate them with several sheets of brown paper. Laying the plants out will often be found a troublesome process, and one which, in order to do it well, will in some cases require time and patience, but it is not of much use to give advice on this head, except to say that the various parts of the flower should be as well exhibited as possible. For instance, where the flower has a colored calyx and no corolla, as in marsh marigold, clematis, and wood anemone, one blossom should be folded up so as to show the absence of the customary row of green leaves below the colored ones. Or the same subject may be effected by completely reversing one blossom, so that its face is towards the paper. Where bracts, or small leaflets at the base of the flower stalks occur, as in orchids, they should be shown. The specimens should be distributed among the sheets of porous paper in such a way that the pressure may be somewhat equal in all places; but those plants, however, are likely to dry more quickly which are nearer the margin of the sheets. Thick stems had better be sliced in half longitudinally, as it prevents their taking up too much room, and also enables them to dry very much faster. The same course may be taken with thick roots or root stocks, as in primrose or coltsfoot; but in such cases care must be taken to leave enough root fibres adhering to the main

axis. Bulbs and corms, and the fleshy tuberous roots of orchids may also be sliced; some recommend scooping out the inside, but this is apt to make them break and spoil under pressure. Berries and stems that are not thick enough to slice may be repeatedly pricked on their under surface, or slashed with the point of a penknife, to let out the moisture. A very good plan with fleshy berries, and thick stems and roots, is to dry them, apart from the rest of the plant, by pressing them between several folds of porous paper, and baking the whole for three quarters of an hour in oven. But this does not always answer, and should not be tried with green leaves, as it is apt to turn them brown. In short, the more rapid the drying process the better; and hence the necessity of having recourse to these contrivances in order that the colors of the blossoms may not be injured through being kept damp by the slow drying of the thicker parts.—*Science Gossip.*

How to Study Entomology.

BY F. C. SMITH.

III.

Continued from page 90.

As far as possible the collector should secure duplicates of all larvæ, thus enabling him to preserve for study the insect in the different stages of its transformation. The caterpillars may be preserved in alcohol or glycerine, using the two or four drachm vials found at any drug store. For future reference, it is well to describe in the record the form, size, color, and peculiar markings of the larva. This will be of great value when ready to name the collection. Text books are published containing the names and descriptions of known species, but it is quite as well to wait until the collection is well started, before spending much time hunting for the names. While at work collecting, mounting, exchanging and putting up specimens, the collector will familiarize himself with the different species, and when ready to classify, name and arrange his cabinet, will consequently more readily recognize the descriptions given in his text-books.

Don't hesitate at all to inform your friends of your doings, and in a short time you will be surprised by receiving specimens from every source. By corresponding with friends at a distance, you can obtain many species common with them but rare with you.

One of the most accessible and pleasing transformations to the young student is that of the *Papilio asterias.* The larva of this butterfly is the common parsley or carrot worm. The color is green, with bands of black and yellow across the back. The feet have black tips. It does not spin a cocoon, but suspends itself by silken threads to the cover of the box in which it is confined, and the change from the larva to the chrysalis takes place very rapidly. In two days from the time it was feeding, it will undergo an entire change, both of form and color. The chrysalis will measure one inch in length, and the butterfly, when hatched, four inches across the wings. In the fall of the year a great number of pupæ may be collected, they being found in nearly every conceivable situation, from the tops of trees to six inches underground, and some even under water. These, if cared for, will reward the collector the next spring with a variety of butterflies and moths that are perfect. There will be no torn or disfigured wings, as oftentimes is the case when taken with a net.

Insects are divided into three parts—the head, the thorax, and the abdomen or stomach. The head is the first division of the body, and is provided with eyes, mouth, antennæ or feelers, and often with a long tongue or probocis. The thorax consists of three segments joined together, and each segment holds one pair of legs. The wings are attached to the posterior segments. The abdomen is always composed of nine segments, and contains the stomach and breathing apparatus.

All insects have six legs, never more or less. The caterpillar, if examined closely,

will be found to have but six true legs. The spider has eight legs, but it is not an insect. This may surprise some of our readers who are not familiar with entomology, but it tends to show that there is a great deal to be learned of the most familiar animals we meet every day.

Another curious fact about insects is that they do not breathe through the mouth, nor even through the head. The breathing holes are called spiracles, and are placed at the sides of the abdomen, usually nine on each side.

Insects that live under water come to the surface for fresh air, with the exception of a few that can live on the air contained in the water.

Some insects possess an incredible number of eyes. If we examine the eye of a fly under a microscope, we will perceive what looks to the naked eye to be but a single eye, to contain hundreds of eyes, of a hexagonal shape, arranged like the cells of honey comb. Each of these is a separate eye, and instead of moving its eye from side to side, as we do, the insect sees with the eyes that are nearest the object. Some of the beetles have 25,000 eyes, the dragon fly 12,000, the house fly 4,000, and the ant manages to see with 50.

The antennæ are two horn-like appendages joined to the head, one on each side, usually in front. Various forms are seen, some smooth and tapering to a point, and some in the form of a club, largest at the small end, while others are broad and branched like a feather.

The antennæ have puzzled entomologists more than any other organ of the insect. They are evidently used as feelers, and some have advanced the opinion that they are the organs of hearing as well. As yet no organs of hearing have been discovered.

To be continued.

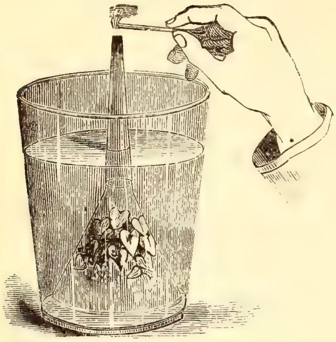
— Among the mechanical toys at the Paris Exposition, are dolls that swim, dive, and tread water, after the most approved human style.

An Interesting Experiment.

THE following experiment requires no special apparatus, and is not only very striking and beautiful, but very instructive. It has been clearly proved that plants breathe, and that by that breath they live. Every green leaf is a delicate lung, and acts the same part in the economy of nature that the lungs of animals do; separating from the air that element which the growth of the plant demands, and discarding or exhaling that which is of no service. And just as oxygen is required by the animal system, so for the support of all vegetable life, carbon is needed. When men breathe, they take into their lungs oxygen, which there combines with the carbon of the blood, forming a third compound gas, known as carbonic acid, which is breathed out, and in this state is of no value, but rather dangerous to animal life. Were there no way of restoring to the air the oxygen which is united to carbon in this gas, then would all animals sicken and die.

But, though the lungs of man and beast are not able to obtain the needed sustenance from the dangerous gas, it is not so with the leafy lungs of the plant. These organs are so formed that they take up freely the carbonic acid; and as, in this case, the food they want is carbon, they retain this, and breathe back or exhale oxygen, which is now free, and ready for man's use again. But how can you prove this fact, that plants breathe out oxygen? The answer is given in the illustration before us; and, as the apparatus used is extremely simple, an explanation of it will best convey our meaning. Having placed in a glass funnel a few fresh green leaves, invert it in a tumbler of fresh water, as here shown. Now close the opening above, and draw off some of the water in the glass. If this vessel be now placed in the sunlight, bubbles of gas will form on the leaves, and rise into the top of the closed funnel. When a sufficient quantity of the gas has so collected, pour in enough water to nearly fill the tumbler, remove the cork, and hold

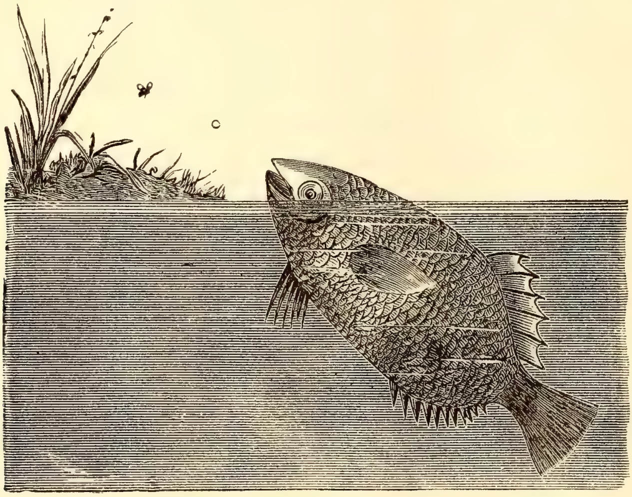
above the opening a glowing match or shaving—that is to say, a match which has a bright spark at the end, but no flame.



The result of this will be, that the gas which comes from the funnel will strike the glowing coal above, and cause it to burn so brightly that it will burst into flame—a result which is evidence, together with certain others, that the gas was oxygen. If carefully performed this experiment almost always succeeds. The best plants are those which grow in the water, either with the leaves submerged or otherwise. They must be exposed to bright sunlight, and two or three days may, in some cases, be necessary to obtain the needed amount of gas.

The Archer-Fish.

FOREMOST in the rank of animal-hunters and trappers, stands the archer-fish, the story of whose skill and cunning is so plainly told by the accompanying illustration. The brook-trout, owing to its slender form and marvellous muscular power, may leap its length above the water, and thus catch its food direct, and with no need of strategy. But with the archer-fish the case is very different. Nature has, it is true, given to it as hearty a love for insect food as is possessed by his more vigorous neighbor, the trout; but, alas, for the gratification of this taste, its body is heavy, and its fins and tail are none too powerful; and so, were there no other means for securing its food, this poor little fish might often go hungry to bed. But the same wise Power which gave to one of His creatures this appetite, provided also means whereby it might be gratified; and this is the way it is done: One of the myriad little bright winged insects, which swarm about the water-plants that fringe the edge of the crystal pool, having finished a sweet feast of honey, leaves behind him the blossoms of the water-thyme and lily, and sails boldly out over the surface of the pond.



THE ARCHER-FISH.

He is too high for the trout, and so there is surely no danger. Perhaps it is the music of his wings, or more likely the the shadow of his body on the water below, that attracts the attention of the little archer-fish, as he roves around among the weeds and pebbles of the pond.

Inspired by the prospect of a hearty meal, this water huntsman arms himself and is off. Slowly he approaches the surface, so directing his course that when his nose rises above the water, it shall be at that point nearest to the game he seeks. No sooner is the surface reached than away goes a little crystal bullet—a drop of water —and down comes the fly. So sure was his aim, and so powerful the force of the blow, that, though often three feet distant, and on the wing, the game is secured and borne down to the home among the pebbles.

The little fish which has so proved his skill as a marksman, is seldom over six inches in length, and is know to naturalists by the name *Texotes jaculator*. It is found in some of the fresh-water lakes of Japan. It is easily domesticated, and when secured in the aquarium, is active in the practice of its art, and seldom fails to capture or bring down the game at which it shoots its crystal bullets.

To Prevent "Day Dreaming."—Study mathematics; engage in solving problems; bring your mind down to matters of fact; read works on natural history, on the natural sciences; give up romance, novels, etc.; try your hand at mechanism; invent and use machinery; finish what you begin, and you will cultivate application and prevent the mind from wandering.

Microscopy.

Canada Balsam Microscopes.

THE article on penny microscopes in the first number of this journal was quite interesting to me, recalling to mind the balsam lenses I have made in times past. Of course these cheap lenses can not be used for scientific purposes, nor their performance be depended on for accurate work, nevertheless they may be made very instructive and entertaining, and with a good book, such as Rev. Wood's "Common Objects of the Microscope," or Lankester's "Half Hours with the Microscope," almost any person can learn enough to pay for the trouble of making the microscope and the money expended for the book.

About two years ago—it was before the summer of 1876—I made and experimented with some of these balsam lenses. I found it difficult to make a lower power than twenty diameters, with good definition, but the higher powers were much more easily made and gave far better results, but they had a very short working distance and were hard to use on that account. I used a pill box with a hole in both bottom and cover. Over the bottom (outside) was a thin piece of mica; on this mica, inside of the box, was a very small drop of balsam. For a diaphragm I used a piece of black tissue paper with a pin hole in it; this was gummed on the outside of the mica—the hole coming under the lens—and the edges turned down around the box, which was then covered with gilt paper. It then presented a very neat appearance.

The highest power I ever made, was three hundred diameters, and it had working distance enough to use No. 1 covers. I used to take considerable pleasure in "fighting" these balsam microscopes against cheap non-achromatic compound microscopes, such as Queen's and McAllister's "Household" etc. The balsam lenses would usually beat!

This morning I came across a box containing four of these balsam microscopes, among them was the one magnifying three hundred diameters. I took a slide of *Stauroneis Phœnicenteron* from my cabinet, and was surprised to see how plainly I could see them. I got a glimpse of the lines but they did not show very plainly until I moved my hand so that sunlight could strike them, when, to my surprise, I

saw them clearly and beautifully resolved. These lines number about 34,000 to an inch.

So much for balsam lenses. If any of the readers of this journal experiment in this direction, I should be pleased to hear what success they have.

ALLEN Y. MOORE.

Tulare, Cal., June 17, 1878.

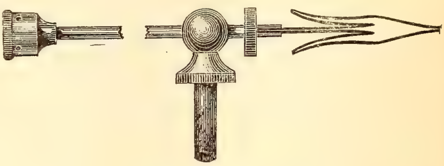
Paste Eels.

IN reply to a correspondent who asks how paste eels may be raised, one of our scientific cotemporaries says that paste, if left to turn sour, will soon swarm with these curious little creatures. The directions usually given are to boil flour and water, as in making ordinary paste, and set it aside until it becomes sour, stirring it occasionally so as to prevent the growth of mould. We have tried this plan over and over again, and have never succeeded once. We have kept the paste until it had passed through all stages of decay, but never, under ordinary circumstances, have eels made their appearance. And, indeed, it would evidently have been impossible to find them, unless they had either been developed by spontaneous generation, or the eggs or germs had been carried through the air. That they could be developed by spontaneous generation, few will believe, and that their eggs or germs are ever carried by the air, we have abundantly disproved by the following experiment: A jar of paste without eels was placed in the centre of six jars containing paste which seemed to be almost alive with them; these seven jars were allowed to stand for weeks, the only addition being a little well boiled (and cooled) water to keep the paste from drying up. Under these conditions the eels in the outer jars throve until the paste seemed to be literally a mass of eels and nothing else. But in the central jar no eels ever made their appearance.

The question arises then, How do the eels ever originate in paste, unless when placed there by design? The only solution that we have found to this question is that they come there from the water used to dilute the paste. It very frequently happens that river, pond or cistern water contains small eels very similar to the paste eel, and it is more than probable that these eels, developing rapidly in the new conditions in which they are placed, cause the paste to swarm with their progeny. Those, therefore, who desire to raise a stock of eels, must, after making the paste, add to it a little water from the bottom of a pond or cistern. In this way a start may often be obtained. But to merely expose a lot of boiled paste to the air until it becomes sour will in almost all cases end in failure. The easiest method, however, is to obtain from some friend a little paste containing eels, and add this to some paste that is three or four days old. The paste should be well mixed, and stirred daily to prevent the growth of mould.

A New Form of Stage Forceps.

THE stage forceps is such a useful and convenient accessory to the microscope that any improvement whereby it is made more perfect or less costly is of value. Mr. George Wale has invented a new form of this little implement, which is shown in the accompanying cut. It will be seen that the forceps proper are made of a single



WALE'S STAGE FORCEPS.

piece of sheet metal bent to a shape which, though easily understood, is peculiar and very difficult to describe. Under ordinary circumstances the forceps remain closed, and take a firm grip of any object placed between their prongs, but by pressing on the wing-like expansions of the metal strip forming the jaws, the latter open and the object falls out. These forceps can be made more cheaply than any others in market.

THE
YOUNG SCIENTIST.
PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ALL COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,
P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers for a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued.

As it is inconvenient to keep book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

Articles in Preparation.

WE have in preparation a large number of very fine articles upon interesting and important subjects. Miss Samuels, of Quincy Point, Mass., has promised to furnish us with a series of articles on the art of Modeling Busts in clay and plaster. We have also a very excellent series on the Lathe, and the best methods of using it, by William B. Harrison, the well-known author of a work on small tools. The series on Botany, Entomology and Photography will also be continued, and we are promised some new and very interesting articles on boat building. An art which is also easily acquired by ladies, and which will enable them to produce very beautiful ornaments on glass by very simple means, will also be fully described and illustrated. Our readers will see, therefore, that we have made ample provisions for furnishing them with entertainment during the coming fall and winter.

Laboratory & Workshop

Crystallization.

Some very striking experiments are easily made with saturated solutions of certain salts. It is a well known fact that although under ordinary circumstances pure water will freeze when cooled to a certain point, it is possible to cool the water much below its freezing point without any formation of ice if we keep it perfectly quiet during the process. Any sudden jar, or the smallest particle of dirt dropped into the water, will start the crystals forming, and the entire vessel will be filled with them in an instant. In winter this is no uncommon occurrence, and it once happened that after a cold still night, the whole surface of a lake was suddenly transformed into a sheet of ice by a slight disturbance near the shore, and the crystals shot out from a point, and could be followed by the eye as they made their way to the other side—a phenomenon witnessed on such a scale by very few. A super-saturated solution is in a condition very much the same as the water cooled below its freezing point, a sudden movement in the latter case suffices to start the crystals forming.

If we take common Glauber's salts, sulphate of soda, which can be bought for a few cents per pound, and add it to boiling water, the water will take up a large quantity. The salt should be added until the water will take up no more while boiling. Remove the vessel from the fire, allow a moment for any suspended matters to deposit, and pour the clear solution, still hot, into a glass vessel, an ordi-

nary flask is as good as anything. Cover the mouth of the flask to keep out dust, and let it cool in a quiet place. When cold, the solution contains much more of the salt than cold water is capable of dissolving; hence it is super-saturated. If the glass is well cleaned on the inside the whole can now be carried about without change, but if we drop the smallest particle of a crystal of Glauber's salt into it, crystallization at once begins, and the contents of the flask become solid. This bit of crystal furnished a nucleus which determined the crystallization. The experiment can be repeated indefinitely by carefully heating the contents again until all the crystals dissolve.

We give another experiment on the authority of Peligot. The proportions are by weight. There are two solutions used—the first contains 150 parts of hyposulphite of soda dissolved in 15 parts of boiling water; the second 100 parts of acetate of soda dissolved in 15 parts of boiling water. Pour the first solution, still hot, into a tall glass, and then pour the second carefully on top, so that the fluids do not mix. Let the whole now cool, protected from dust. When we wish to see the crystals form, tie a small crystal of the hyposulphite on the end of a thread, and lower it into the vessel until it reaches the bottom solution. It will at once determine the crystallization of this. Drop now a crystal of the acetate into the upper solution, and this also will solidify, but the form of the crystals will be very distinct from the others. H.

How to Make an Æolian Harp.

One of our subscribers having requested us to describe a good method of making an Æolian harp, we give the following, which has been tested and found to work admirably: Of very thin cedar, pine or other soft wood, make a box five or six inches deep, seven or eight inches wide, and of a length just equal to the width of the window in which it is to be placed. Across the top, near each end, glue a strip of wood half an inch high and a quarter of an inch thick, for bridges. Into the ends of the box, insert wooden pins like those of a violin, to wind the strings around—two pins in each end. Make a round hole in the middle of the top, and string the box with small catgut or blue first fiddle strings. Fastening one end of each string to a metallic pin in one end of the box, and carrying it over the bridges, wind it round the turning pin in the opposite end of the box. The ends of the box should be increased in thickness where the wooden pins enter, by a piece of wood glued upon the inside. Tune the strings in unison, and place the box in the window. It is better to have four strings, as described; but a harp with a single string produces exceedingly sweet notes, which vary with the force of the wind.

Hints on Filing.

The following practical directions for using the file are extracted from "A Treatise on Files," recently published by the Nicholson File Company, and will be found of great value to amateurs:

Height of Work.—Various ideas very naturally exist amongst mechanics, as to the height at which the jaws of the vise should be set from the floor, for use in filing; arising largely, no doubt, from the varied nature of the work upon which the advocates of the different ideas have been accustomed to operate.

For filing general work, the top of the vise jaws should be placed so as to be level with the elbow of the workman, which will be found to range from 40 to 44 inches from the floor—therefore 42 inches may be considered as an average height, best suited for all heights of workmen, when the vise is to be permanently fixed.

If the work to be filed is small and delicate, requiring simply a movement of the arms, or right hand and arm alone, the vise should be higher, not only in order that the workman may more closely scrutinize the work, but that he may be able to stand more erect.

If the work to be filed is heavy and massive, requiring great muscular effort, its surface should be below the elbow joint; as the operator stands further from his work, with his feet separated from 10 to 30 inches, and his knees somewhat bent, thus lowering his stature; besides, in this class of work, it is desirable to throw the weight of the body upon the file, to make it penetrate, and thus, with a comparative fixedness of the arms, depend largely upon the momentum of the body, to shove the file.

It will therefore be seen that in fixing the height of the vise, the nature of the work and the stature of the operator should be considered, if it is deemed necessary to apply the principle correctly.

Grasping the File.—In using the larger files, intended to be operated by both hands, the handle should be grasped in such a manner that its end will fit into, and bring up against, the fleshy part of the palm, below the joint of the little finger, with the thumb lying along the *top* of the handle, in the direction of its length; the ends of the fingers pointing upwards, or nearly in the direction of the operator's face.

The point of the file should be grasped by the thumb and first two fingers, the hand being so held as will bring the thumb, as its ball presses upon the top of the file, in a line with the handle, when heavy strokes are required. When a light stroke is wanted, and the pressure demanded becomes less, the thumb and fingers may change their direction, until the thumb lies at a right angle, or nearly so, with the length of the file; the positions changing more or less, as may be needed to increase the downward pressure.

In holding the file with one hand, as is often necessary in filing light work, pins, etc., the handle should be grasped as already described, with the exception that the hand should be turned a quarter turn, bringing the forefinger on top, and lying along the handle nearly in the direction of its length. In this position, the freest action of the hand and wrist may be had upon light work.

Amateurs will find that by following these directions, the movements of the file will be simplified, and made somewhat easier than if grasped at random and without consideration.

Correspondence.

Drawing Boards.

Ed. Young Scientist—I have used drawing boards for many years; I used to think they must have cleats on the ends or back. When strong cleats are put on, as you direct, there is little or no advantage in gluing up the board from narrow strips; but where the board is so glued up, there is no occasion for any cleats; indeed it is better without them. The cleats confine the parts to which they are attached to one unvarying width, while the parts between the cleats are, in a measure, free to expand and contract with alterations of the hygrometric conditions to which they are exposed. Consequently the edges of the board cannot remain straight.

A double elephant board made of 4-inch strips, and 1¼ inches thick, will be abundantly strong without cleats; it will not warp enough to be troublesome, and the edges will stand much better than if made as you direct. It has the additional advantages of being cheaper, lighter, less bulky, and of having either side available. J. B. S.

BOOK NOTICES.

A Treatise on Files and Rasps: Descriptive and Illustrated. For the use of Master Mechanics, Dealers, etc.; in which the kinds of Files in most common use, and the newest and most approved special tools connected therewith are described, giving some account of their principal uses. With a description of the process of manufacture and a few hints on the use and care of the file. Published by the Nicholson File Co., Providence, R. I.

Although intended chiefly as a means for advertising the files of the Nicholson File Company, this handsome quarto volume contains a great deal of valuable practical information upon the subject of files in general and their use. It is well illustrated, and must prove a valuable addition to the library of any mechanic.

Current Notes.

Iridescent Glass.—Some specimens of ancient glass are remarkable for the exquisite iridescence which they display, some of them surpassing in beauty the colors on the neck of the dove. A recent number of "Le Propagateur," in commenting on this new iridescent glass, makes the following remarks in regard to its manufacture: "In Germany the glass to be iridized is heated, and a metallic oxide deposited on its surface by reduction. The oxide forms striæ on the surface, and these determine the phenomenon of iridescence. Bismuth seems to be much used in the principal glass works as the iridizing metal. In fact, M. Peligot, the eminent chemist, who has analyzed these iridescent glasses, found appreciable quantities of bismuth in them. Any metal whatever might, perhaps, produce the same result."

Indelible Indian Ink.—Draughtsmen are well aware of the fact that lines drawn on paper with good India ink which has been well prepared, can not be washed out by mere sponging or washing with a brush. Now, however, it is proposed to take advantage of the fact that glue or gelatine, when mixed with bichromate of potassa, and exposed to the light, becomes insoluble, and thus

renders India ink, which always contains a little gelatine, indelible. Reisenbichler, the discoverer, calls this kind of ink "Harttusch," or "hard India ink;" it is made by adding to the common article, when making, about one per cent, in a very fine powder, of bichromate of potash. This must be mixed with the ink in a dry state; otherwise, it is said, the ink could not be ground up easily in water. Those who cannot provide themselves with ink prepared as above in the cake, can use a dilute solution of bichromate of potash in rubbing up the ink; it answers the same purpose, though the ink should be used thick, so that the yellow salt will not spread.

Hatching Alligator Eggs.—The New York Aquarium has received from Florida a large number of alligators' eggs, and has made arrangements to hatch them artificially. This will prove an interesting and instructive experiment. It is expected that a young alligator will emerge from its shell every hour during the day, affording every visitor a chance to see the curious sight. This experiment will be the first of the kind ever tried, and should it prove successful, will be of considerable scientific importance. The attempt to keep California salmon alive during the hot weather has been successful. Heretofore these invaluable fish have invariably died during the summer months. At the Aquarium one of the tanks has been turned into a refrigerator, and these fish are now perfectly healthy.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Wanted, a 5 by 8 stereoscopic camera box; Fleetwood scroll saw, nearly new in exchange. L. L. Roberts, 1,203 Arch street, Philadelphia, Pa.

Wanted, good microscope and Vols. I and II of "American Journal of Microscopy, or thorough works on botany; thorough instruction in shorthand, by mail, in exchange. T. S. Price, King's River, Cal.

Wanted, in exchange for books, a second-hand aquarium. Address P. O. Box 124, Bridgeton, N. J.

A collection of postage stamps for small cannon or small printing press; will pay difference. C. L. Hackett, lock box 2,210, Roanoke, Ind.

To exchange a good magic lantern, painted slides, cost $8, for a music box of same price, in good order. L. D. Snook, Barrington, Yates Co., N. Y.

McAllister's Household microscope and American Agriculturist microscope, for small 5 or 6 inch turning lathe, or offers. J. Frank Weaver, Brooklyn, Conn.

Graham's Handbook, Synopsis, and 1st and 2d Readers Standard Phonography; tools or advanced scientific books preferred in exchange. E. H. Bidwell, Vineland, N. J.

Magic lantern, nine slides (two mechanical) in complete order, in exchange for good compound microscope. T. R. Barwood, Flatbush, L. I.

Complete outfit for stamping key checks, worth $10, in exchange for practical receipt books, or bracket saw with lathe and drill attachment. John Whitty, Jr., Polloksville, N. C.

Woodward's Hospital Microscope wanted in exchange for chemical scales and weights; difference in cash. J. Siler, 1,212 Broadway, St. Louis, Mo.

For exchange, an entire printing outfit, cost $50; state what you have to exchange. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Good $50 job printing press, in perfect order, for a scroll and circular saw, or scroll saw alone; saw must be in good order. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, foot power scroll saw, lathe, or both combined, or good microscope, for minerals, books on plant culture, Art Journal in parts, or cancelled postage and revenue stamps. D. S. Kimball, 48 Exchange Place, New York.

Wanted, small steam engine and boiler of from 1 to 2 horse-power; state what is wanted in exchange. Address Jno. McElvery, Flatbush, L. I.

Wanted, telegraphic and mathematical instruments; Pitman's Phonography in exchange; also thorough instruction in same by mail. F. S. P., King's River, Fresno County, Cal.

A set of chemicals and apparatus; also a set of wood engraver's tools, glass and instruction book, to exchange for a scroll saw and a microscope. The chemicals and tools cost nearly $40; will give a good trade. F. H. Jackson, Angelica, N. Y.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a small turning lathe in exchange for a pair of telephones. J. C., care YOUNG SCIENTIST.

Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Wanted, complete Lester combination scroll saw in good condition; books in exchange. J. T. Jackson, Box 48, Metuchen, N. J.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

Wanted, microscope, or scientific and mechanical books and apparatus, in exchange for printing press, cost $21, with or without type and material. J. P. Burbank, Salem, Mass.

Cigar machine to exchange for bracket saw or good microscope. Leonard Alexander, Linneus, Me.

Wanted, microscope; new Tillotson relay and part cash given in exchange. W. O. F., 83 Downing street, Brooklyn.

To exchange, a Kidder electric battery, for a private line telegraph instrument. Charles L. Feldkamp, 200 W. Randolph street, Chicago, Ills.

Camera for taking portraits wanted; state what is wanted in exchange. J. F. H., care of this journal.

VOL. I. NEW YORK, SEPTEMBER, 1878. No. 9.

How to Make Indian Canoes.

BY WM. B. HARRISON.

THE term "canoe" is of Indian origin, and is applied to boats made of bark, or the body of a tree hollowed and made into suitable shape for sailing purposes. The civilized so-called "canoe" is but a cheap, portable yacht, often clinker built, and bearing little resemblance to the canoe of savage manufacture.

In places where the white birch, or "canoe" birch grows to perfection, there the bark canoe is the favorite. Its chief merits are ease of construction and lightness; the latter an essential quality where portage is necessary, a bark canoe twelve or fourteen feet long being easily carried on the shoulders of one man, while one of twice that length is easily carried by two men.

The cheapest form of canoe is made of spruce, elm, hickory or bass wood bark. It is constructed by peeling the bark from a section of the tree, say twelve or fourteen feet long, and about eighteen or twenty inches in diameter. It is not necessary to fell the tree to obtain the bark. It is first girdled at the top and bottom for the length desired. The outside bark may be shaved off or not, as may be convenient. Then cut perpendicularly from girdle to girdle, and start the bark at the girdles with wooden wedges. Be careful and not split the bark. When peeled, let it down carefully from the tree, and spread flat on a level place, with the rough side uppermost. The inside of the bark is made the outside of the canoe. As the ends are to be closed together, shave thin at these ends, and, folding the bark, bring them together in the manner shown in Fig. 1, and tie a half round stick on each side to hold them thus, binding firmly both at top and bottom. By means of an awl, or bodkin, to make the holes, sew together the ends that project beyond the half-round sticks. Make the stitches crossing each other. When firmly sewed, cut off the sticks near the bark leaving enough to hold

the fastenings that bind them together. The next thing is to make two laps on each side, inclining toward the stern, as shown at *a*, *a*. This gives shape to the body of the canoe. As shown in Fig. 2, fit two thin strips, *c*, *c*, on each side of the gunwale, and fasten at bow and stern. Keep these apart by means of cross sticks, as at *b*, *b*. Shape the canoe, as near as possible, with stakes, sods or stones. Beginning in the middle, place ribs under the inside gunwale strips, fasten them, and continue bending until the bottom is reached, then bend up on the other side to the gunwale, cut off square and fasten firmly. Strings made of hickory, elm or bass wood bark, are used for binding. The paddle is shown in Fig. 3. The seat for the paddler or passengers must be in the bottom of the canoe. To sit otherwise would be at the risk of overturning.

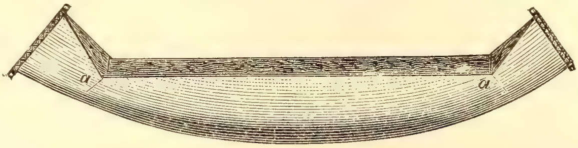

Fig. 1.

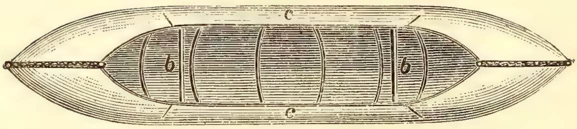

Fig. 2.

Fig. 3.

In building a canoe of birch bark (Fig. 4), the gunwales are first made of thin strips, preferably of cedar, about one-quarter inch thick and about one inch wide. One is to go on each inside, and one on each outside edge. The covering is prepared by sewing pieces of the bark together, which can be readily done before it gets dry and hard. The length of the canoe is then measured off on the ground, and stakes driven there, two at each end. The bark covering is then folded lengthwise, the inside of the bark outward, and the ends inserted and held between the stakes. The ends must project enough to allow a strip of bark to be folded over the ends and then firmly sewed from top to bottom. The gunwale strips are then placed in position, the bark placed between the pieces and there sewed. Cross pieces are placed between the gunwales to keep the sides in shape, as at *d*, *d*. The inside is then shaped, and lined lengthwise with thin strips of cedar, and strengthened with ribs which are placed crosswise, then bent down to the bottom, and so tied and fastened. The seams of the bark are smeared with pine gum or pitch.

The Ojibways had another method of making canoes. They dug a hole in the ground, the exact shape of the canoe to be built. Strips of thin wood about three inches wide, like barrel hoops, were laid crosswise of the excavation, and pieces of like shape were placed lengthwise. These pieces were then pressed into the hole and tied together, the hole being a sort of mould in which to press the strips, and so retain them until fastened, when they would keep this shape. The framework was then lifted from the hole, turned bottom side up, the covering of white birch bark laid over

it, folded in place and tied there. The caulking of the seams was done by a squaw holding the pitch in her mouth until softened, drawing it out into strings, placing it on the seams, and smoothing it down with a fire-brand. The Ojibways made twine from basswood bark by soaking the bark in water until nothing was left but the flaxy fibre. This was then twisted into cords and strings, to be used for canoe making and other purposes.

The log canoe (Fig. 5) is made from pine, whitewood, black ash, basswood and cottonwood. Pine is the best. After the tree is felled, the top and bottom of the intended canoe is shaped. The outline or gunwale lines of the sides are then marked out and shaped, the rule being to make the length into three sections, one being the bow, one the middle or body, and one the stern. A greater width in the middle gives ease of motion when sailing. After the exterior form of the canoe is made and finished, the inside is hewn or burned out. It can be made quite light by making the sides and bottom thin.

The bark canoe of the form given in Fig. 4 is considered the best. An improvement in the bark covering may be made by substituting sheet zinc. It is lighter, more lasting, less liable to become leaky, capable of greater speed, and may be made more symmetrical. A canoe of this kind about eighteen feet long, eighteen inches deep, and about three feet wide, may be made so as to weigh about fifty pounds, and will be capable of carrying seven or eight persons. Three sheets of fourteen-pound zinc will make the covering. Cut the zinc so that there will be four pieces, three feet eight inches long and three feet wide. Curve or round off the longest sides about three-fourths of an inch at the ends, to nothing in the middle. Bend the pieces up to nearly as possible the shape of the inside of the canoe. Stay them so with a strip or two, and solder them with tinner's solder, using muriate of zinc as a flux. If the two middle sheets be made proportionately wider than the others, when bent up, lapped about one-fourth of an inch and soldered, and the edges properly rounded, the bottom will be of the proper curve. Place the other pieces, one on each end of these two pieces, and solder in like manner. Take two other pieces of zinc, fold them together like the ends of the bark canoe, solder one end of each, and fit the open end to the pieces already soldered; mark how they should fit, cut properly, lap and solder. There will be four spaces left at the corners of the curve, which will have to be covered with pieces cut to fit and then soldered. Remember to solder well, both inside and outside. Place two thin strips of wood, one on each side of the zinc, at the upper edge for gunwales; form a curve outwards and upwards, and nail through both strips

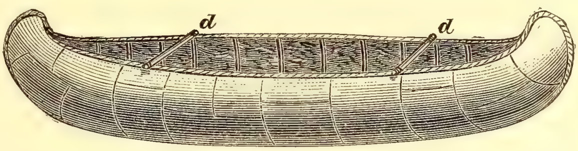

Fig. 4.

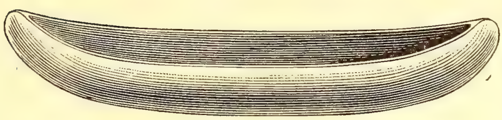

Fig. 5.

and zinc. Put in thin ribs, the same as in the bark canoe, and stay them with rivets. Paint any color to suit the fancy. The paddle used is the same as for the bark canoe.

To make the paddle (Fig. 3), take a strip of light wood, about three feet eight inches long, make the blade one-half the length of the paddle, and four or five inches wide. Make it thin, so as to spring. The paddle is used on one side of the canoe, and is never crossed only to change hands for a rest.

How to Make an Herbarium.

BY JOHN W. BUCK, B. SC.

Continued from page 104.

IN speaking of laying out the specimens, I omitted to give one hint which may be of service; I refer to the judicious use of the scissors. It will sometimes be found advantageous to cut away leaves and blossoms from what we may call the back of the plant, when there are too many of them, and when they would conceal one another's shape by their number. It has the effect also in many cases of making the specimen look more natural, since, when growing, the branches of a bushy plant do not incommode one another, but spread out equally on all sides. A bunch of berries—those of the spurge laurel, for example—must generally be partly cut away. Sometimes it is well to postpone the operation until the specimen is dry and ready for mounting. But be very cautious that in cutting you do not disfigure the plant, or deprive it of some important feature. Every plant has its characteristic kind of inflorescence, or flower arrangement, and also of leaf-arrangement, and if you snip away recklessly you will produce effects that will sadly puzzle any botanist who may afterwards look over your collection.

The pressure necessary for the thorough preservation of the plants may be caused by large books laid over the papers, with a few bricks on top, or by strapping the papers together between two strong boards. The latter plan I prefer, and almost always make use of, because the whole affair can be carried about from place to place if required, or set before a fire to dry quicker, which is often a great convenience. I need hardly say that, however the plants are pressed, they should always be in as dry a place as possible. As regards the amount of pressure to be applied, it should be borne in mind that the object is not to squash the plants, but to keep them flat and dry them; and hence, especially with succulents, a too excessive pressure should be avoided. If, however, enough paper be interposed, and the specimens well distributed among the sheets, ordinary plants will take no harm under any reasonable pressure.

In transferring the plants, when changing the sheets of porous paper, it will be found advantageous not to lift up each plant by itself and place it on another sheet, but to adopt the following plan. After having lifted away the damp sheets above the plant—which must be done with great care, by turning them slowly back with the right hand, while guiding and moderating the operation with the left, which should be held down on the upper surface of the paper you are removing,—place a dry sheet over the plant. Then take up the two uppermost sheets, with the plant between them, carefully invert them, lay them on the pile of dry sheets, and lastly skin off the damp sheet in the same way as before. Even by this method it will not be found easy to keep the blossoms and leaves of some plants smooth, as they are so apt to stick to the papers. All blossoms that are at all troublesome had better be dried separately; and in the case of such as poppies, they should be protected by a couple of pieces of tissue paper, which should not be removed until the drying process is quite over. The chief difficulty in transference will be found only while the plants are damp, and will disappear entirely as they get drier. The damp sheets should be completely dried before using them again, by exposing them to warm, dry air.

There are several ways of judging when

the plants are dry. In the first place, a thoroughly dry plant is generally rigid, unless it be very long and weak. Feeling of the plant by the lips, or placing the hand on the sheet of paper from which it has just been taken, are other tests, but in these cases you must distinguish between coldness and dampness. Generally speaking, you may rest satisfied that if the specimen has been under pressure, with dry and frequently changed papers, for eighteen or twenty days, it is likely to be quite dry, unless its nature is such as to make the matter doubtful.

Now comes the mounting, which should not be deferred, as postponing it probably means spoiling the specimens and losing the labels, and certainly means an accumulation of work at some future time. For fixing the plants, some recommend the application of hot glue; but this is very troublesome to manage, and as the operation of carefully gluing a large specimen is rather a long one, the glue is not likely to be very hot when the time comes for fastening it down. Strong gum answers quite as well and is more convenient. To make the gum, take one ounce of picked gum arabic, as colorless as possible, powder it, and stir it with a clean stick or a glass rod in an ounce and a half of cold water until it is dissolved; add a quarter of an ounce of powdered gum tragacanth ("gum dragon"); and lastly, add two grains of corrosive sublimate, previously dissolved, along with two grains of sal ammoniac, in one drachm of water. A metal stirring-rod should not be used, as it is apt to discolor the liquid. The latter, if carefully made, is quite colorless, and does not show much, if any be accidentally smeared. (N. B.—Corrosive sublimate is very poisonous, and the bottle of gum containing it should be labeled "Poison.")

To be continued.

—Prince Leopold, the youngest son of Queen Victoria, has written a book upon the Polarization of Light, which is to be published during the present year.

Simple Lessons in the Art of Photography.

THE SILVER BATH.

Continued from page 92.

THE cause that so many amateurs fail completely in photographing may, in nine cases out of ten, be traced to the silver bath. Any one not practically acquainted with photography will undoubtedly be greatly surprised on being informed that more mistakes will occur in making the silver bath than in compounding any other liquid used in photography. The whole secret of making a good silver bath that will produce clear negatives and keep its good properties for a reasonable time, lies in the application of heat, in one form or other, in order to effect a chemical mixture of the nitrate of silver in water.

It is true that nitrate of silver is readily dissolved in water in greatly varying proportions, but without the action of light or heat the mixture will rather be mechanical than chemical, and the results obtained with such a bath will be entirely unsatisfactory. Nitrate of silver of chemical purity can be bought either from druggists or dealers in photographic materials at such a comparatively low price that it will not pay to incur the trouble of making it. Distilled water is not absolutely necessary, but under no circumstances should spring water be used. Ice water or rain water do very well.

The best way to proceed in making a silver bath is as follows: First clean from all impurities, by means of sulphuric or nitric acids, the bottle which is going to serve as a temporary receptacle for the silver solution. Select a bottle of white glass. Fill the bottle with 12 ounces of water, and dissolve in it 1 ounce nitrate of silver. The bottle should now be placed for ten or twenty hours in the full sun, where the liquid will gradually change into red brown, or even black, and finally, after the settlement of some dark-colored sediment on the bottom of the bottle, the fluid will exhibit the purest crystalline transparency. The settlement of the sediment is the sign that

the process of purification is complete, and that the nitrate of silver is dissolved. While this is going on, it is advisable to stir the mixture occasionally.

By the direct application of heat, the same object can be accomplished. The liquid is poured into a porcelain or glass vessel, gradually heated, and kept boiling for from 10 to 20 minutes. In order to avoid a reduction of the given quantity of the silver solution by evaporation, the nitrate of silver should be dissolved in 14 ounces of water. In the latter operation the impurities will float on the water. As soon as the liquid, if it has been boiled, is cool, or if treated by the first method, is transparent like crystal, two grains of iodide of potassium, dissolved in a drachm of water, are added, and by frequent stirring thoroughly incorporated into the silver solution, which is then left undisturbed for half an hour. At the expiration of this time the solution is filtered through double filtering paper into another clean bottle, where even the most careful inspection should be unable to discover the slightest impurities. The addition of one drop of nitric acid will insure clear negatives and prevent fogginess. Repeated stirring, and a rest of half an hour, will be found also indispensable to effect a thorough union of the acid with the silver solution.

The silver bath is now ready for use, and will keep in good order for a longer or shorter time, according to the degree of cleanliness and care with which it has been treated.

Sometimes the addition of another drop of nitric acid will be found necessary to prevent fogginess, but generally only in cases where the water used for the nitrate solution is strongly alkaline.

The silver solution should be slightly acid. Litmus paper, which can be had in every drug store, should, in contact with the bath, turn only slightly red.

The silver solution should be completely saturated with iodide. This second point can be tested by the addition of some weak solution of iodide of potassium in water, which, in case of previous saturation, will render the liquid turbid. The silver solution should be free from every odor or smell.

With proper care 12 ounces of bath will sensitize 50 to 80 quarter plates. Small baths generally require a second or third addition of iodide after a number of plates have been dipped, an inconvenience to which larger baths are not liable.

THE DEVELOPER.

In the wet collodion process, there are two developing solutions, the protosulphate of iron developer, and pyrogallic acid developer.

Formulæ for iron developer: 1. Water, 16 ounces; protosulphate of iron, 1 ounce; acetic acid, ½ to 1 ounce.

2. Water, 16 ounces; protosulphate of iron, 1 ounce; pure sulphuric acid, 1 to 2 drops.

The iron salt is pulverized and intimately mixed with the given quantity of rain water. Add now the acid, when, after filtering, the solution is complete. If the developer does not flow well, half an ounce of alcohol should be added.

The quantity of acid that must be used depends upon several circumstances. In summer, when the temperature is high, it has to be increased, while in cold weather it may be diminished. The action of the iron salt without acid is too energetic and unmanageable. As a general rule, long exposure requires a weak developer, while short exposure, especially instantaneous pictures, demand a very small quantity of acid. Too large a quantity of acid will produce fogginess. The presence of acid exercises also a certain influence upon the character of the whole deposit: the more acid the finer the deposit, and conversely the less acid the grosser the granulation. Diminishing the iron salt in the same quantity of water also weakens the reducing properties of the developer, though a certain quantity of acid is always necessary to prevent fogginess.

Formula for pyrogallic acid developer: 6 grains pyrogallic acid; 6 grains citric

acid; 3 ounces water. The pyrogallic acid and the citric acid are dissolved in water when the solution is ready for use. This solution does not keep very well, and should always be prepared fresh. This developer requires a longer exposure than the iron developer, and is more appropriate for negatives than for positives. The quantity of citric acid can be modified to the same circumstances which regulate the treatment with acetic acid in the iron developer.

In making either positives on glass, or ferrotypes, it is desirable to have a white, metallic-looking film. The addition of one drop of nitric acid, 10 grains nitrate of potassa, and a few drops of silver solution to the first formula, will accomplish the desired end.

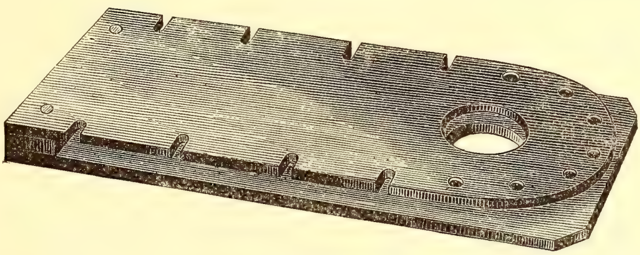
The developer renders the latent picture upon the collodion film visible. It produces a decomposition of the silver solution in such a manner as to leave the metal in a reguline condition only on those places which have been acted upon by light.

Microscopy.

A New Form of Frog-Plate.

THE circulation of the blood in the foot of the frog has always been a favorite subject for exhibition. The subject is so easily prepared, and it may be seen by such ordinary instruments, that few persons who own a microscope need be deterred from attempting to see it themselves, or to show it to others. Of the many forms of apparatus specially designed for holding the frog and displaying its foot, the common brass frog-plate has been most generally used, but it has this disadvantage, that after the frog has been properly secured, it is almost impossible to move the plate under the clips, which, in the cheaper microsoopes, serve to retain the object in place on the stage. A very simple addition to the ordinary frog-plate serves to remedy this defect, and enables the observer to bring under view any part of the web of the foot.

This frog-plate consists of two plates firmly rivetted together at one end, with a strip between them which holds them a little more than an eighth of an inch apart.



A NEW FORM OF FROG-PLATE.

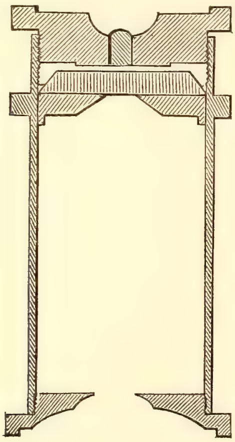
The under plate is plain, with a hole which corresponds with the hole over which the web of the foot is stretched. This lower plate passes under the clips of the stage, which retain it securely, but allow perfect freedom of motion. The frog, after being swathed in a strip of moistened muslin, is tied to the upper plate, the notches at the side of which hold the windings of the string from sliding. Around the large hole over which the web is spread, there are several holes, the object of which is as follows: After the frog has been tied to the plate, its position being so regulated that the web of the foot will come fairly over the hole, the operator takes three pieces of thread, each having a slip-knot at the end. These slip-knots are passed over the toes and drawn tight; the free ends are passed through such of the small holes as are best

adapted to spread the web, and by means of small wooden pins, are fixed there. It is well to place a piece of very thin plate glass or thick covering glass under the foot, which must be kept thoroughly saturated with water. After considerable use of this frog-plate, we find it the most convenient we have ever used. It may be made of any suitable material; our first was made of an old cigar box, and then we had some made of brass, but we find that hard rubber is superior to anything else.

A Collecting Microscope.

THINKING that anything new in the way of microscopes may interest the readers of this journal. I send you a sectional cut (full size) of an immersion collecting microscope, recently made for me by the Spencers, of Geneva, N. Y.

I have found it quite valuable when after desmids, diatoms, etc., as it is a compressorium and animalcule cage, as well as a



microscope of seventy-five diameters. The metal part is of well finished brass.

When the mounting of the lens is screwed down as far as it will go, the front surface of the lens comes in contact with the thick glass stage. This latter is beveled around the edge, similar to a first-class animalcule cage, and when the screw is slightly oiled, objects in fluid may be kept for a long time, as it is then air-tight, and evaporation prevented. The focus of the lens is at its plane surface.

The drawing makes any further description unnecessary. ALLEN Y. MOORE.

Tulare, Cal., July 9, 1878.

Pond Hunting.

THE writer has frequently, and probably in common with many other microscopists, thought with regret of the truth of Mr. Crouch's assertion before the Quekett Microscopical Club, to the effect that pond life is a subject with which American microscopists are generally but little acquainted, *Volvox globator* being an unfamiliar object to many. Granting that the *volvox* is not as common here as in England, as is undoubtedly the case, for the writer has, during the last three Summers, explored the ponds and ditches considerably without finding it, the substance of the charge is only too true. The reason may be urged that the Americans are too practical and busy a people to spend time exploring puddles and ditches where neither funds or fame are to be found, but even microscopists find time for amusement now and then. The national dislike to walking, and an equally characteristic aversion to open air pastimes generally, are no doubt among the principal reasons for the neglect of a flora and fauna full of interest and beauty. Our running streams and still lakes alike offer new species to the collector, and it certainly seems to the writer that no object can sooner bring its reward of absorbing interest to the individual, and no branch of microscopical study requires less previous preparation or accessory apparatus.

In the course of a walk along Forty-fourth street, near the lake shore, Chicago, a short time ago, a little pool, barely two yards wide, was observed, from which ran a rill of not more than a teacupful capacity. A dip of the vial brought up at least a dozen little green atoms, nothing else but *volvox*, while further queries with the dipping bottle resulted in a find of the greatest variety of animal and vegetable life. Mr. Atwood, one of the party, names the following

among the entomostraca and infusoria: Cyclops quadricornis, Canthocampus minutus, sundry of the cypris tribe, Actinophrys sol, Rotifer vulgaris and Anguilula fluviatalis, while among the algæ Mr. Colgrove reports: Oedogonium mirable, Chætophora elegans, fragments of nostoc, Closterium lunula, C. acerosum, Cosmarium teteropthalmum, C. Botrytis, Euastrum verrucosum, Staurastrum punctuatum, several species of diatoms, and the volvox.

Two, at least, of the party had never seen a live *Volvox globator* before, and if not unduly enthusiastic at the sight of the little living globe rolling gracefully across the field of the microscope, did not restrain their exclamations when one gave birth, in a Cæsarean style, to a family of eight, each of which, after a moment's rest, set their cilia in motion, slowly at first, afterwards more rapidly, and moved away on their voyage of life.

Now the moral of this little tale is two-fold—First, do not remain in ignorance of the beautiful forms that fill with life the ponds and streams around us, for instruction may be gleaned by the student, and entertainment by the dilettante from them; and, second, always take a collecting bottle when you go out walking.

Rules for Using Glue.

Glue, being an animal substance, it must be kept sweet; to do this it is necessary to keep it cool after it is once dissolved, and not in use. In all cases keep the glue-kettle clean and sweet, by cleansing it often.

Good glue requires more water than poor, consequently you cannot dissolve six pounds of good glue in the same quantity of water you can six pounds of poor. The best glue will require from one-half to more than double the water that is required with poor glue, which is clear and red, and the quality of which can be discovered by breaking a piece. If good, it will break hard and tough, and when broken will be irregular on the broken edge. If poor, it will break comparatively easy, leaving a smooth, straight edge.

In dissolving glue, it is best to weigh the glue, and weigh or measure the water. If not done there is a liability of getting more glue than the water can properly dissolve. It is a good plan, when once the quantity of water that any sample of glue will take up has been ascertained, to put the glue and water together at least six hours before heat is applied, and if it is not soft enough then, let it remain longer in soak, for there is no danger of good glue remaining in pure water, even for forty-eight hours.

The advantage of frozen glue is that it can be made up at once, on account of its being so porous. Frozen glue of same grade is as strong as if dried.

If glue is of first-rate quality, it can be used on most kinds of wood work very thin, and make the joint as strong as the original. White glue is only made white by bleaching. E. N.

A Story of Science.

BY ONE WHO KNOWS NOTHING ABOUT IT.

A philosopher sat in his easy chair,
  Looking as grave as Milton;
He wore a solemn and mystic air
  As he Canada balsam spilt on
A strip of glass, as a slide to prepare
  For a mite taken out of his Stilton.

He took his microscope out of his case,
  And settled the focus rightly:
The light thrown back from the mirror's face
  Came glimmering upward brightly.
He put the slide with the mite in place,
  And fixed on the cover tightly.

He turned the instrument up and down,
  Till getting a proper sight, he
Exclaimed—as he gazed with a puzzled frown—
  "Good gracious!" and "Highty-tighty!
The sight is enough to alarm the town—
  A mite is a monster mighty!"

From t'other end of the tube, the mite
  Regarded our scientific,—
To its naked eye, as you'll guess, the sight
  Of a man was most terrific,
But reversing the microscope, made him quite
  The opposite of magnific.

"One sees the truth through this tube so tall,"
  Said the mite as it squinted through it,
"Man is not so wondrously big after all,
  If the mite-world only knew it!"

MORAL.

MEM.—Whether a thing is large or small
  Depends on the way you view it!

Fun.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

ALL COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers as a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued.

As it is inconvenient to keep book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

A Liberal Offer.

EVERY one knows that the greatest obstacle in the way of extending the circulation of a new journal, provided it has any merit, is the difficulty of bringing it before those who are likely to subscribe. In proportion to the results obtained, miscellaneous advertising is too expensive, for those who are likely to take a journal like ours are in a comparative minority. Thus far, however, our success has been quite encouraging, and now, in order to increase this success still further, we have determined to enlist the efforts of every one of our present subscribers by the following liberal offer, which, be it remembered, applies only to those whose names are now on our books.

Any subscriber sending us two new names, with the money—$1.00—will receive his own copy for 1879 free. That is to say, we will, to our present subscribers, give three copies for one dollar.

In doing this we have two objects in view. In the first place we are anxious to extend our circulation as much as possible, and in the second we desire to acknowledge our sense of the good feeling which has prompted so many to support a new, and to them untried enterprise.

During the coming months we expect to make the YOUNG SCIENTIST more than ever worthy of the support of its readers. Our draughtsmen and engravers have their hands full of good things in store for the journal, and as we intend to enlarge the journal permanently next year, adding four more pages, we feel confident that during 1879 both our readers and ourselves will have "a good time."

Laboratory & Workshop

Hints on Filing.

Carrying the File.—The most natural movement of the hands and arms in filing, is to carry the file in circular lines, the several joints of the limbs being the centres of motion; this movement of a convex file would apparently give a concavity to the work. The real tendency, however, especially on narrow work, is the reverse, (owing to the work acting as a fulcrum, over which the file moves with more or less of a rocking motion,) giving an actual convexity to its surface, except when in the hands of a skilful operator. The real aim, therefore, should be to cause the file to depart

only so much from a true line as will be necessary to feel that each inch of its stroke is brought into exact contact with the desired portion of the work.

The movements here referred to, have reference to those in which both hands are used upon flat work, requiring nicety and trueness of finish, and the difficulties to be overcome in producing even a comparatively true flat surface with a file, require much practice on the part of the operator.

In filing ovals and irregular forms, the movements, while not considered so difficult or trying, nevertheless require considerable experience, and a good eye, to so blend the strokes of the file upon the round or curved surfaces, as to give the best effect; the varied nature of the work upon this class of surfaces, though much might be said, prevents any detailed definition as to the movements of the file, within the limit of this article.

In point of economy, the pressure on the file should be relieved during the back stroke; this will be apparent to any one who will examine the formation of the points of the teeth, when it will be seen that the file can only cut during the ordinary or advancing stroke, and that equal pressure during the back stroke must be very damaging to the points of the teeth.

Draw-filing.—Files are sometimes used by grasping at each end, and moving them sidewise across the work, after the manner of using the spoke-shave. This operation is known as draw-filing, and is usually performed in laying the strokes of turned work lengthwise, instead of circular, as left from the lathe finish, as well as when giving a final fit to the shaft that is to receive a coupling—cases, generally, in which no considerable amount of stock is to be removed. Thus, any defects in the principle of construction, or arrangement, of the teeth of the file, are not so readily apparent.

Files, as they are ordinarily made, are intended to cut when used with a forward stroke, and the same file cannot work smooth, or to the best advantage, when moved sidewise, unless care is taken that the face of the teeth present themselves, during the forward movement of the file, at a sufficient angle to cut, instead of scratch the work. To accomplish this, the angle at which the file is held, with respect to the line of its movement, must vary, with different files, depending upon the angle at which the last, or up cut is made. The pressure should also be relieved during the back stroke, as in ordinary filing.

When properly used, work may be finished somewhat finer, and the scratches more closely congregated, than in the ordinary use of the same file; as in draw-filing the teeth produce a shearing or shaving cut.

First Use of a File.—In economizing the wear of files intended for general purposes, consideration should be given to the kind of material which they may be subjected to in the different stages of their use.

In the ordinary use of the machine shop, the first wear of these files should be in finishing the larger surfaces of cast iron, bronze, or brass metals, all of which require a keen cutting tooth; they may then be made to do good execution upon the narrower surfaces of these metals, also upon wrought iron and soft steel; although to obtain the best results, the file suited for general purposes is not so well adapted to filing brass, or other similar soft metals, as those whose teeth are arranged for this purpose.

Mucilage.—A good mucilage to be used for pasting newspaper clippings into scrap books, and one that will not cause the paper to become transparent to the detriment of the reading, may be made by putting a few cent's worth of gum tragacanth into a wide-mouth vial or a small jar, and turning in water sufficient to a little more than cover the gum. Before putting in the water, add a little acid to it; a few drops of vinegar or sulphuric acid will do. This will prevent decomposition and a disagreeable smell. If desired a few drops of any essential oil may be added to impart an agreeable odor.

The American Institute.—The exhibitions of this association have for more than half a century constituted the "Permanent Exhibition" of New York, and whether considered as a means of education, through the display of valuable products and processes, or as a most effectual means of bringing to the notice of the public the novelties which are brought forward every year, the Institute Fairs have always stood foremost amongst the exhibitions of this country—always, of course, excepting the Centennial. The Exhibition opens this year on the 11th of September, and those who desire to avail themselves of its advantages should make haste to address the Secretary, whose office is in the Cooper Union building.

Inquiries and Answers.

Inquiries.

32. Can you give me a recipe for making fusible metal that will melt in water? Also, how is artificial coraling done on wood or metal? ***

33. Can any of your readers tell me the proportions of sulphate of ammonia and nickel for making an electroplating solution? A. W. P.

34. Please state through the columns of THE YOUNG SCIENTIST, a cheap outfit for mounting insects for the microscope. SUBSCRIBER.

35. Do you know of a dissolvent or a softener of printer's ink when dry? I want to take impressions on glass of scientific and other pictures for lantern slides, as many are very desirable and not in any catalogue of slides. C. I. S.

36. An acquaintance of mine has a knife with his name eaten into the blade by some kind of acid. Will some one tell me what kind of acid is used for this purpose, and how to apply it? B. G. P.

Answers.

37. In answer to J. N. H. (29), Watts gives the following solution for gold and silver plating without a battery: 1 oz. of nitrate of silver dissolved in 1 quart of rain or distilled water. When thoroughly dissolved, add a few crystals of hyposulphite of soda, which will at first form a brown precipitate, but which redissolves if sufficient hyposulphite has been employed. The solution may be used by simply dipping a sponge in it, and rubbing it over the article to be coated. A solution of gold may be made and used in the s me manner. W. J. A.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

A small steam engine in good order, cost $1.50, for a dark (bulls-eye) lantern. Geo. H. Umbach, 139 Ross street, Brooklyn, N. Y.

Wanted, a set of wood engraver's tools; Spencer's Psychology, two volumes, given in exchange; also other books for exchange. T. S. Price, Slack's Cañon, Monterey Co., Cal.

Wanted, small turning lathe about 1½ by 12 ins.; state what is wanted in exchange. D. Abrahams, 195 East Broadway, New York.

Globe microscope, magnifies 100 diameters, cost $2.50 to exchange for a book on shorthand, or offers. George R. Simpson, Janesville, Bremer Co., Iowa.

Wanted, back numbers of the "American Naturalist;" will give "Harper's" or "Scribner's" monthly. —— Hulbert, 131 West Fifty-third street, New York.

Wanted, a 5 by 8 stereoscopic camera box; Fleetwood scroll saw, nearly new in exchange. L. L. Roberts, 1,203 Arch street, Philadelphia, Pa.

Wanted, good microscope and Vols. I and II of "American Journal of Microscopy, or thorough works on botany; thorough instruction in shorthand, by mail, in exchange. T. S. Price, King's River, Cal.

Wanted, in exchange for books, a second-hand aquarium. Address P. O. Box 124, Bridgeton, N. J.

A collection of postage stamps for small cannon or small printing press; will pay difference. C. L. Hackett, lock box 2,210, Roanoke, Ind.

To exchange a good magic lantern, painted slides, cost $8, for a music box of same price, in good order. L. D. Snook, Barrington, Yates Co., N. Y.

McAllister's Household microscope and American Agriculturist microscope, for small 5 or 6 inch turning lathe, or offers. J. Frank Weaver, Brooklyn, Conn.

Graham's Handbook, Synopsis, and 1st and 2d Readers Standard Phonography; tools or advanced scientific books preferred in exchange. E. H. Bidwell, Vineland, N. J.

Complete outfit for stamping key checks, worth $10, in exchange for practical receipt books, or bracket saw with lathe and drill attachment. John Whitty, Jr., Polloksville, N. C.

Woodward's Hospital Microscope wanted in exchange for chemical scales and weights; difference in cash. J. Siler, 1,212 Broadway, St. Louis, Mo.

For exchange, an entire printing outfit, cost $50; state what you have to exchange. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Good $50 job printing press, in perfect order, for a scroll and circular saw, or scroll saw alone; saw must be in good order. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, foot power scroll saw, lathe, or both combined, or good microscope, for minerals, books on plant culture, Art Journal in parts, or cancelled postage and revenue stamps. D. S. Kimball, 48 Exchange Place, New York.

Wanted, small steam engine and boiler of from 1 to 2 horse-power; state what is wanted in exchange. Address Jno. McElvery, Flatbush, L. I.

Wanted, telegraphic and mathematical instruments; Pitman's Phonography in exchange; also thorough instruction in same by mail. F. S. P., King's River, Fresno County, Cal.

A set of chemicals and apparatus; also a set of wood engraver's tools, glass and instruction book, to exchange for a scroll saw and a microscope. The chemicals and tools cost nearly $40; will give a good trade. F. H. Jackson, Angelica, N. Y.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Wanted, a small turning lathe in exchange for a pair of telephones. J. C., care YOUNG SCIENTIST.

Scroll saw wanted in exchange for handsome portfolio of six water color sketches. Address F. S., care Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Wanted, complete Lester combination scroll saw in good condition; books in exchange. J. T. Jackson, Box 48, Metuchen, N. J.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

Wanted, microscope, or scientific and mechanical books and apparatus, in exchange for printing press, cost $21, with or without type and material. J. P. Burbank, Salem, Mass.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. I. NEW YORK, OCTOBER, 1878. No. 10.

Wood-Carving.

THE art of carving wood is one that is very fascinating, and, at the same time, very easily learned. Indeed, many ladies have adopted it as a recreation, and have thus been enabled to add greatly to the numerous articles of *vertu* which ornament the parlor and the boudoir. Some branches of the art are exceedingly simple, requiring but a few hours and the employment of the simplest tools, to enable even a beginner to turn out very respectable work. On the other hand, some departments of the same employment require for their successful pursuit the highest skill of the sculptor and the artist; and thus there is abundant room offered for the exercise of the very highest talents, while even those of very ordinary abilities will find no difficulty in securing that success which alone can confer enjoyment. In this respect, wood-carving differs from many merely routine operations, in which differences of skill are hardly appreciated. The most talented and skilful may find full scope for their abilities, while even the least ingenious will find that they can actually accomplish respectable work. We therefore propose, in the following articles, to give such simple yet complete instructions as will enable any smart boy or girl to take up the art, and pursue it as far as their abilities will allow.

The first thing to be provided is a proper set of tools, and fortunately these are neither numerous nor expensive. Here is an ample list for a beginner: three chisels—eighth, quarter and half-inch; three flat gouges, do.; three deeper gouges, do.; three half-round, do.; one V, or parting tool; one sken, or corner-chisel; one mallet; two cramps for fastening the work to the table; one oil-stone; one slip; one brace and bit, for boring holes; two fine gimlets; two punches—one star and the other checquer; one tracing-point; a small glue-pot; a few small files; and a hammer. The cost of the entire outfit is but a trifle; and many of the tools—such, for example, as the brace and

bit and the hammer—may be found in the tool-chest of most ingenious boys. In making the purchases, however, beware of what are called "boy's" tools. They are cheap and pretty, but the material and temper are not what is required. Go, therefore, to some respectable hardware shop, and purchase such tools as are sold to mechanics—with good large handles, and finely though not fancifully finished—and you will have a set of really much more serviceable tools than any assortment that is

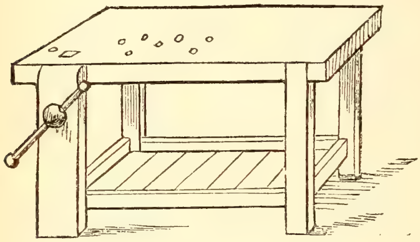


Fig. 1.

usually put up for amateurs. A few of the tools—including the punches and the V or parting tools—can be had only from houses that deal in wood-carver's tools, but they may be ordered through any hardware merchant.

Any good stout table will answer for a work bench; but if you can procure a bench as made in the engraving (Fig. 1) it will greatly facilitate your operations. It should

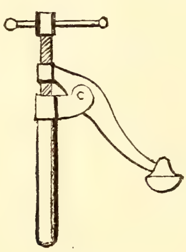

Fig. 2.

be at least forty inches long by twenty-four wide, with a bench-vice at one end, and a tray at the further side to hold the tools. The thickness of the bench should be at least two inches, and it should be as firm and as solid as it can be made. It should be high enough for you to stand up to your work; and have holes bored through at convenient distances, in three rows, to insert the hold-fast, of which a sketch is given (Fig. 2). The hold-fast is put into one of the holes, the work to be held is put under the pad, and the screw is turned until the work is firmly fixed. This hold-fast is used when the wood to be carved is too thin for the carver's screw to be inserted into it, and when it is not desirable to glue it down on another board. In using this hold-fast, we always put a piece of some soft wood between the pad and the wood that we are carving, so as to prevent the teeth of the pad from marking it. It is not difficult to see that a deep scratch might interfere sadly with the delicate part of some leaf. Instead of the hold-fast, the carver's screw, which is better, may be used. It all lies below the table, and there is nothing in the

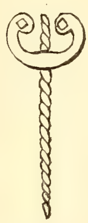

Fig. 3.

way of the carver. This screw, with its nut or clamp, is shown in Fig. 3. To use it, remove the clamp, grasp the screw in the bench vice between two scraps of wood, so as to save the jaws of the vice; screw the upper or sharp point into the block to be carved; pass the screw down through the bench, and then, by means of the clamp or nut, make it fast. Where the block is very thin, it should be glued to a thick block, a thickness of paper being glued between the two to facilitate their separation, as will be hereafter described.

The bench that we use is a compound of a carver's and joiner's bench, and we can strongly recommend it to all amateurs who

can afford to have one made; for, after having carved your work, you can joiner it, and you can plane and prepare your own wood, and be thus independent of the carpenter, which is most desirable. Our bench is of the following dimensions: Length, 4 feet 5 inches; breadth, 3 feet 1 inch; height, 3 feet 1½ inch. The wood is oak, three inches thick, and there are three rows of holes for the hold-fast. There are only two holes in each row; the centre of the holes of first row, three inches and a half from the edge, and fourteen inches from head of bench. There is the usual bench-stop, or dog, and the bench-vice is of the ordinary pattern, which may be procured at any hardware store, and is easily fitted up.

To be continued.

How to Make an Herbarium.

BY JOHN W. BUCK, B. SC.

Concluded from page 117.

TO mount the specimens, lay them on a sheet of brown paper or newspaper, gum them carefully all over the back, and then lay them gently on the white sheet in the best position, which you should have previously decided on, and press them down with a clean handkerchief. Use no more gum than is absolutely necessary, and wipe away any excess at once. A good plan with a very large or weak plant is to gum the back of the stem, fix it by a gentle pressure, and then turn up the leaves and flowers one by one, gum them, and then lay them back again in position. Another method, which I remember trying once with a long trailing pimpernel, and which succeeded well, was to gum it on the back as before; shift it, still face downwards, to a sheet of brown paper the same size as that on which I was going to mount it, arrange it as I desired, and lastly turn the white sheet down over it. On lifting it up, it of course brought the specimen away with it. The delicate blossoms which have been separately dried should next be placed in their natural position, care being taken to hide any awkward appearance of a join in the stem. Long plants, too long to lie on one sheet, should be cut in two pieces, and these laid side by side; and if the stem be very long and a piece of it be permanently removed, the cut ends should not be brought close together, but it should plainly appear that a piece of the stem is absent. All parts of the plant should be shown as far as they can, and on the same sheet. For instance, somewhere on the dandelion sheet should be shown the globular downy seed-head, and with the strawberry plant the strawberry fruit itself, which latter, notwithstanding its succulent nature, may be easily dried, if not too ripe to begin with. These should not be made to appear as if growing from the same plant as in flower unless they were actually found so growing. In fact, in mounting such parts, nature must be imitated, not contradicted. A few slips of well-gummed paper of the same kind as that you are mounting upon, should be kept at hand, with which to fix down stiff stems, which often have a tendency to part company with their sheets.

Labeling should be done immediately after mounting. To keep the names, localities and dates of the plants while pressing, the particulars may be written on small scraps of paper, which must be transferred each time with the respective specimens whenever the sheets are changed. I have found this plan answer best in practice, as, if the entries are made in a note-book, there is a danger of afterwards mistaking one plant for another. But however these facts are preserved, as soon as a specimen is fairly mounted, they should be transferred to the right-hand bottom corner of the permanent sheet. They may be written thus:

Rhinanthus Crista-galli,
(Yellow-rattle),
Hayfields, near Freshford,
10. 6. 78.
(Collector's name.)

Or printed labels may be obtained with spaces to be filled up. After mounting and labeling, the sheets should be again pressed flat for a day or two.

But the young botanist who does not wish to have a good deal of trouble thrown away, and to see his well dried specimens devoured by insects, has more work before him yet. Mould is not likely to trouble him with plants which have once been made completely dry. A botanical friend, to whom I am indebted for several of these hints, writes: "At one time, in the very wet summer of 1875, and when I had my press so full that scarcely more than two sheets were between plant and plant, I found, to my disgust, many of them moulding. But I took heart, and brushed off the mould with a moderately stiff brush continually, till they were thoroughly dry, and then stacked them away between dry sheets, and did not look at them again till nine months afterwards, when I found them without a particle of mould. Later on, I cured some of the mould by brushing it off and washing the plants with corrosive sublimate, while they were still in the press. But, by pressing few at a time, and by using more paper, I might, of course, have escaped that; and it does not do to trust to being able to get rid of the mould so, for it discolors the specimens." But all plants are more or less liable to the attacks of insects, and some, as the *Ranunculaceæ*, *Cruciferæ*, and *Umbelliferæ*, especially so. The best preventive is corrosive sublimate. The Rev. Gerard Smith recommends dipping *Ranunculaceæ* (buttercups) and *Cruciferæ* (shepherd's purse, cuckoo-flower, etc.) before pressing, into a saturated solution of corrosive sublimate in equal parts of rain water and methylated spirits. A more convenient plan is to paint the specimens with the liquid after they are mounted. For this purpose a solution should be made of one-quarter of an ounce of the sublimate in half a pint of methylated spirit (not "methylated finish,") which is to be applied to the specimens with a pretty stiff brush, taking care that it penetrates all corners and crevices. Every plant should be treated in this way, as it not only prevents the attacks of insects in the future, but entirely destroys any animal life that may be already there. The sheets are then to be again subjected to pressure for twelve hours, after which they will be ready for the herbarium.

It only remains now to arrange the specimens in proper order, but as it is unnecessary to do this until a large number have been collected, we will leave the consideration of it at present. Meantime the sheets should be laid flat in a box, secured from dust, kept in a dry place, and not exposed to the light more than necessary.—*Science Gossip.*

How to Study Entomology.

BY F. C. SMITH.

IV.

Continued from page 105.

INSECTS are divided by most naturalists into nine orders. These orders are again divided into families, and the families into species.

The orders are as follows: *Aptera*, *Diptera*, *Hemiptera*, *Lepidoptera*, *Orthoptera*, *Hymenoptera*, *Thysanoptera*, *Neuroptera* and *Coleoptera*.

Insects of the order *Aptera* are wingless, and embrace fleas, lice, etc. All insects which suck their food, and possess but two membranous wings are called *Diptera*. Most insects of this order have two very minute appendages, in the absence of the second pair of wings, called poisers, their duty being to regulate the flight of the insect. The *Hemiptera* are four winged, in some species membranous, and in others the upper wings are of a harder consistency than the lower. The order *Lepidoptera* embrace the insects commonly known as the butterfly and moth. These insects are remarkable for their beautiful colors, and are found in great variety in all parts of the world. They undergo three complete transformations. Cockroaches, locusts, grasshoppers, crickets, etc., are of the order *Orthoptera*. The anterior wings are usually long, narrow, and half horny, and serve only as a protection for the secondary wings, which are more delicate and used for flying only. The metamorphoses

of this insect is incomplete. Those insects having four membranous naked wings lying horizontally upon the body are embraced in the order *Hymenoptera.* Bees, wasps and ants are of this order, and undergo a complete transformation. The *Thysanoptera* have not received much attention from naturalists, there being but few insects of this order yet discovered. The *Neuroptera* is an order comprised chiefly of dragon flies, and presents the greatest number of modifications of form of any order known. The easiest preserved order is the *Coleoptera,* and in large collections this order usually holds the first place. About one hundred and thirty thousand species are already found, and constant additions are made to this order, which embraces beetles of all kinds.

The orders *Coleoptera* and *Lepidoptera* are almost sure to be the first to attract the attention of the young student, and in a brief review we will consequently notice these orders before taking up the others.

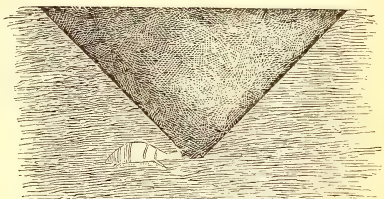
Let us first examine a caterpillar, which is an imperfect insect of the order *Lepidoptera.* We will find the body to be composed of twelve segments or parts. First is the head, containing the mouth and six simple eyes. Next comes the three segments which are to constitute the thorax of the perfect insect, be it moth or butterfly, containing the six true legs. The rest of the segments constitute the abdomen. The legs on these parts are not true legs, but simply organs of locomotion, armed with minute hooks, by which a firm hold is obtained to a twig or leaf. Nearly all caterpillars feed on plants, the exceptions being those that infest our furs and woolen fabrics. After attaining its full growth, the caterpillar ceases to eat, and prepares for the wonderful change that is about to take place. The intestinal canal is emptied of all vegetable matter, and its colors lose their brilliancy. The pupa state is now entered upon in one of three manners, depending on the species: either by suspending itself by the tail to a leaf or branch, and by a series of convulsions, emerging a chrysalis; or by spinning a cocoon of silk around itself, and undergoing the change inside the cocoon; or by burrowing in the soft earth and entering the pupa state underground. These astonishing and wonderful changes will form the most attractive and instructive department of the study of the insect world.

To be continued.

The Ant Lion.

IN a recent number we gave an account of the very singular method by which the archer fish secured its prey. Amongst the hunters of this class, the ant lion occupies a prominent position, and an account of it cannot fail to interest our readers.

This ravenous little insect is endowed by nature with superior intelligence, and displays great skill and cunning in the entrapping and securing of its prey. Having determined upon a suitable site, generally a clear sandy space under the shade of some shrub or boulder, it begins the construction of a minature pitfall by first thrusting



THE ANT LION.

its long jaws and flat head underneath the grains of sand, and then by a sudden upward jerk tossing them several inches beyond the edge of the pit. This operation is repeated until a funnel-shaped hole is excavated, as shown in the plate, the sides of which are as steep as the shifting nature of the sand will allow.

When completed, the ingenious little builder conceals his body at the bottom, leaving only the extended jaws exposed. Here he awaits patiently until the unconscious victim, generally some smaller insect, approaches the edge of the ambuscade,

when the disturbance of the sand above warns the watcher below, and he begins to toss up the earth from beneath the unwary ant or beetle, thus deepening the hole, and causing the sand on the shelving sides to slide down toward the centre, bearing with it the prey to within reach of the extended jaws. The lower sides of these are provided with tubular channels, that serve as ducts to convey the blood of the victim to the mouth of the captor. After sucking the body dry, the carcass is tossed beyond the limits of the pit, which is at once repaired, and made ready for the approach of a second visitor.

Simple Lessons in the Art of Photography.

FIXING SOLUTIONS.

Continued from page 119.

THE last important solution used in photogrophy is the fixing solution. Without fixing solutions, the image invisibly printed by the actinic rays of light reflected from the object, and rendered visible by the developer, would soon fade away and entirely disappear. Experiments indefatigably carried on for more than ten years were required before fixing solutions—the last keystone in the arch of photographical operations—were discovered. The fixing solutions at present in use are: cyanide of potassium and hyposulphite of soda.

Cyanogen does not exist either in a free or combined state in nature; it is a production of decomposition in which the elements contained in it are brought together in the nascent state. It is a gas which, by a pressure of four atmospheres, is reduced to the liquid state of the numerous combinations which it forms. Hydrocyanic acid or prussic acid, and cyanide of potassium, are the most important; the latter of the two is the only one used in photography. The extraordinarily poisonous character of this compound renders its use rather dangerous. Hyposulphite of soda, which possesses the same degree of dissolving power, without the poisonous qualities of the former salt, is obtained by digesting sulphur in a solution of sulphite of soda.

Formula No. 1, (poisonous). Cyanide of potassium, 1 drachm; water, 4 ounces.

Formula No. 2. Hyposulphite of soda, 2 ounces; water, 4 ounces.

The photographic properties of cyanide of potassium and hyposulphite of soda which are called into action, are their power to dissolve the iodide and bromide in the sensitized collodion film, which have not been affected by light. Cyanide is not only a solvent, but also a reducer, a fact which accounts for the whiteness in the silver film when the plate has been fixed by its application. For this reason it is regarded as the fixing agent peculiarly adapted for collodion positives; whereas in the negative, where the whiteness of the silver film is of little or no consequence, hyposulphite of soda is regarded as the proper fixer.

Negatives fixed by the latter salt require a very thorough washing, since if any trace of it is left in the film, the image will be destroyed by crystallization taking place on its surface.

How to Sharpen a Screwdriver.

IN driving a screw into wood, the force used to press the screwdriver against the head of the screw, tends to aid the latter in penetrating the wood, but when we attempt to extract a screw, every pound of pressure that we apply tends to render it more difficult to get the screw out. It therefore becomes very important that the screwdriver should be so formed that it may be kept in the nick of the screw by the exertion of the very least degree of force; for if it has any tendency to slip out, we can keep it in place only by applying pressure, in which case we run great risk of injuring the nick and rendering it impossible to draw the screw. If we examine a screwdriver in the condition in which it is ordinarily found, we shall find that it presents a section like that shown in Fig. 1, in which the sides of the wedge, in which all screwdrivers terminate, are curves with the convex sides outwards, Now, the effect of

thus curving the sides of this wedge, is to render it greatly more obtuse. Moreover,

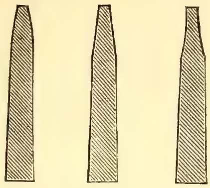


Fig. 1. Fig. 2. Fig. 3.

when we turn the screwdriver, the tendency to slip out of the nick is just in proportion to the obtuseness or bluntness of the wedge, and therefore this form is the very worst that can be chosen. In the hands of most good workmen, therefore, we find that the screwdriver ends in a wedge of which the sides are perfectly straight, like Fig. 2. This is a very good form, but is not equal to Fig. 3, in which the sides of the wedge are curves, but with the *concave* sides turned outwards. In this way we lessen the obtuseness of the wedge at the extreme point, and produce a turnscrew which may be kept in the nick by the least possible pressure endwise. To grind a screwdriver into this form, it is necessary to use a very small grindstone, and many of the artificial stones found in market answer admirably. Amateurs would find it to their advantage to keep one of these small grindstones for this and similar purposes, as it can be run in the lathe with very little trouble.

The Effect of Politeness.

A BRAVE, active, intelligent terrior, belonging to a lady friend, one day discovered a monkey belonging to an itinerant organ-grinder, seated upon the bank within the grounds, and at once made a dash for him. The monkey, who was attired in jacket and hat, awaited the onset with such undisturbed tranquility that the dog halted within a few feet of him to reconnoitre. Both animals took a long, steady stare at each other, but the dog evidently was recovering from his surprise, and about to make a spring for the intruder. At this critical juncture the monkey, who had remained perfectly quiet hitherto, raised his paw and gracefully saluted by lifting his hat. The effect was magical; the dog's head and tail dropped, and he sneaked off and entered the house, refusing to leave it till he was satisfied that his polite but mysterious guest had departed. His whole demeanor showed that he felt the monkey was something "uncanny," and not to be meddled with.—*Nature.*

To Remove Tight Stoppers.

To remove glass stoppers when tightly fixed, it has been recommended to apply a cloth wet in hot water. This is an inconvenient and frequently unsuccessful method. The great object is to expand the neck of the bottle so as to loosen it on the stopper. If, however, the latter be heated and expanded equally with the former, the desired effect is not produced; and this is often the case in applying hot water. By holding the neck of the bottle about half an inch above the flame of a lamp or candle, for a few seconds, we have never failed in the most obstinate cases. The hands should be wrapped in a towel, and great care should be taken not to let the flame touch the glass, as this might cause it to crack. The bottle should be kept rapidly turning during the operation, so as to bring all parts of the neck equally under the influence of the heat, when it will be rapidly expanded, and the stopper may be withdrawn by a steady pull and twist. Following this plan, we have never failed once out of hundreds of attempts. When the bottle contains alcohol, benzine, ether, or similar inflammable liquids, great care must be taken lest the stopper should come out suddenly, and the contents of the bottle take fire.—*Amateur's Handbook.*

Preserving the Colors of Pressed Plants.

The following process is said by the London *Chemist and Druggist* to give very excellent results: Dissolve one part of salicylic acid in 600 parts of alcohol, and heat the solution to the boiling point in an evaporating dish. Draw the plant slowly through the liquid, wave gently in the air to get rid of superfluous moisture, and dry between folds of blotting-paper several times repeated. In this manner the plants dry rapidly, which is a great gain, and they thus furnish specimens of superior beauty.

The Heavens for October.

BY BERLIN H. WRIGHT.

THE computations in the following are made for the meridian of New York city, and are expressed in mean or clock time:

How to Find and Recognize the Major Planets and their Telescopic Appearance.—The major planets should always be looked for in the Zodiac, a belt extending 8° on each side of the sun's path. The only ultra-zodiacal planets are the asteroids or minor planets, which are invisible to the naked eye.

The planets, unlike the stars, come into view at no particular season of the year, and are almost constantly changing their position among the stars, advancing or moving eastward, and apparently retrograding or moving westward at different times. There are times, however, when they do not change their position, relative to the stars, for several days, owing to the fact that their motion in orbit is then in the direction of the line of vision. Hence, if upon observing a body in the Zodiac for several successive evenings, we find it changing its place with respect to the neighboring stars, it must be a planet or comet. This method will only apply to Mercury, Venus and Mars. The motion of Jupiter, Saturn and Uranus past the stars being too slight to be easily observed, while Neptune is invisible to the naked eye.

There are nine major planets, including the newly discovered intra-Mercurial planet and the earth, and 186 minor planets. We will mention them in their order outward from the sun.

Vulcan can only be seen during an eclipse of the sun, darkening the sky in its vicinity, and then only with the aid of a telescope.

Mercury is so close to the sun that he can only be seen either during a solar eclipse and near greatest elongation, *i. e.* when his angular distance from the sun is greatest. Even when the elongation is greatest, he can not always be seen, owing to the fact that he is south of the sun part of the time, and consequently his altitude (perpendicular distance above the horizon) at sunrise or sunset would be much less (for the same amount of elongation) than when north of the sun.

When brightest, there are few stars that equal him in brilliancy. At a recent conjunction of Jupiter and Mercury, it was impossible for us to identify them by any difference in brilliancy.

To the amateur telescopist Mercury presents but few features of interest. A telescope of very moderate power will show his phases. His phase when brightest, is generally very slightly more than a half-circle. He will be brightest Sept. 28, rising at 4h. 27m. morn—1h. 26m. before the sun, and 6 minutes after the beginning of twilight—about 8° north of the sunrise point. He will be in conjunction with Venus Sept. 30. Their conjunction in right ascension occurs about 9 o'clock in the morning, and as Mercury has at that time the greatest apparent eastward motion in R. A., he will, when first seen, be east of Venus. Venus will be the brighter, and south of Mercury about one-fourth of a degree. He will not be visible again until December.

Venus, to the eye, is the most beautiful of the planets, but when viewed with a telescope sadly disappoints the observer, especially if a high power be used and the instrument is not approximately achromatic. When brightest she may be seen with the naked eye at noonday.

Any ordinary telescope or good opera glass will show her large crescent when brightest, and a little better instrument will show all of her phases.

She is a morning star, remaining such until Dec. 5, when she reaches superior conjunction. Hence she now presents a large gibbous phase, or is nearly full, as we apply the term to the moon. She rises as follows:

1st—4h. 33m., morning.

10th—4h. 57m., morning.

20th—5h. 21m., morning.

30th—5h. 45m., morning.

We have only mentioned the inferior planets, or those situated between the earth and sun. Next month we will conclude this description.

Penn Yan, N. Y., Sept. 4, 1878.

Microscopy.

A Common Microscopic Object.

AMONGST the most common, as well as the most interesting of microscopic objects are the bell-shaped animalcules (*Vorticella nebulifera*). They are to be found in almost every pool of water, and, indeed, in every old bucket used to draw water from wells and cisterns. They are therefore amongst the first objects which present themselves to young microscopists, many of whom, when they first see them, think they have discovered a new organism of rare and surpassing beauty, for they cannot see how a creature so exquisite and interesting can be known at all, and yet not be known to everybody. Those who desire to study the life history of these curious creatures, will find a pretty full account of them in Gosse's "Evenings with the Microscope," and in Carpenter's treatise. It requires no great power to see the animalcules themselves, or even to detect the curious wheel-like motion of their cilia, by means of which they obtain their food, but to see the cilia themselves, that is, the little hair-like processes which are seen to fringe the mouths of the bell-shaped cups in the engraving, requires a good glass. The word *cilia* means literally *eye lash,* and these lashes when put in motion create a sort of whirl-pool or vortex, which sucks in any little floating particles, and carries them into the interior of the animalcule, any nutriment that they may contain being absorbed, and the insoluble parts rejected. These cilia are put in motion one after the other in a continuous round, and this gives an optical appearance exactly like the motion of a wheel. A similar effect in another and nearly allied organism, has given it the name of the *wheel animalcule.* These little creatures are very sensitive, and the least jar produces a curious effect upon them. They at once stop all motion, and the long stalk upon which they are mounted instantly contracts, assuming the spiral form seen in two of the individuals shown in the engraving. After a short time they again begin to expand, the wheels resume their motion, and the process of feeding goes on as before. No one ever sees this object for the first time without being enchanted with it.

GROUP OF BELL-SHAPED ANIMALCULES (*Vorticella Nebulifera*).

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

TO ADVERTISERS.

The YOUNG SCIENTIST has been received with so much favor that its circulation is already greater than that of any other monthly Scientific or Mechanical journal published in the city of New York, with the exception of the *Popular Science Monthly*. It goes into the best families, and has their confidence. NO CLAP-TRAP ADVERTISEMENTS, OR ADVERTISEMENTS OF PATENT MEDICINES RECEIVED AT ANY PRICE.

ADVERTISING RATES—30 cents per line, nonpariel measure.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers as a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued. As we keep no book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

A Liberal Offer.

AS an acknowledgment of past liberality on their part, and an incentive to future efforts on our behalf, we shall give his own copy for 1879 free to every subscriber who is now on our books and who will send us the names of two new subscribers and $1.00. That is to say, we will, to each of our present subscribers, give three copies for one dollar.

What we are Doing.

WE give in this number the first of a series of notes on the celestial objects that may be seen during the following month. This will enable our young friends to watch the bright winter skies with a deeper interest than even their extraordinary beauty can call forth. We also begin a series of articles on wood-carving, which we think will enable many of our readers to take up an art which in some departments is quite simple and easily learned.

Next month we shall, in addition to other valuable matter, give the first instalment of an article on Modeling in Clay, by Miss Samuels. This article will surprise many of our readers by its simplicity. Modeling in clay is generally regarded as a very difficult art, and one requiring a long apprenticeship before even the most commonplace results can be attained. Miss Samuels shows how, even from the beginning, very fair work may be turned out by a little patience and care.

As we stated some months ago, it requires considerable time, and a great deal of labor and money to bring a journal like ours up to the ideal which we have set before us. No other journal of the kind has ever been published to our knowledge, and consequently there is nothing which we can take for a pattern. But from the liberal encouragement which we have received, we feel assured that there is a well-defined want for such a periodical, and we are determined to use our best endeavors to supply it.

Laboratory & Workshop

Hints on Filing.

Preparing Work.—The corners or thin edges of iron castings are very likely to become chilled, and a thin scale or skin produced over the entire surface of the casting, caused by the hot metal coming in contact with the moist sand of the foundry moulds; this outer skin is usually much harder than the metal beneath it, and many times the thin edges or corners are chilled so as to be harder even than the file itself.

The necessity, therefore, of removing this scale and chilled surface, becomes readily apparent, and all mechanics who give any consideration to the proper and economical use of the file, will be careful to see that the scale and sand are first removed by pickling, and the surfaces which have become chilled, by grinding, before applying the file.

Pickling the Work.—The pickle for gray iron castings is generally made by mixing sulphuric acid and water, in the proportion of two or more parts of water to one of acid, and is usually kept for this purpose in a trough lined with lead.

The articles to be pickled are sometimes immersed in this bath, where they are allowed to remain for a short time; they are then removed, and the acid is allowed to act upon their surfaces until the scale is loosened, when they are washed off with water. More often, however, the pickle is dipped from the trough, and poured over the castings, which are placed on a sloping platform (thus allowing the acid to return to the trough), where, after remaining for a sufficient time, they are then washed. When dry, the castings are either rattled, or scraped and cleaned with old files and wire scratch-brushes, until the surface is freed from scale and sand.

To pickle brass, or gun-metal castings, a mixture of nitric acid and water may be used, in the proportion of, say one part acid to five of water, the treatment being the same as that of the iron castings. While not in general use upon the coarser kinds of brass work, the pickle is desirable for smaller castings, or those requiring to be protected with lacquer.

When Oil should not be Used.—All files, when they leave the manufactory, are covered with oil to prevent them from rusting. While this is not objectionable for many uses to which the file is put, there are cases where the oil should be thoroughly removed, as when the file is to be used in finishing the larger cast iron surfaces, which are of a glassy nature, the principal difficulty being, to make the file "bite," or keep sufficiently under the surface to prevent glazing; otherwise the action not only hardens or burnishes the surface operated upon, but dulls the extreme points of the teeth, thus working against the desired end in both directions.

When Oil may be Used.—Oil may, however, be used to good advantage on new files, which are put immediately to work upon narrow fibrous metals of a harder nature; in such cases, it is not uncommon, with good workmen, to fill the teeth with oil and chalk.

Oil is also useful on fine files, in the finishing of wrought iron, or steel, as by its use the teeth will not penetrate to the same degree, and the disposition to "pin," and scratch the work, is materially less than when used dry.

Cement for Stone or Marble.—The best cement for mending marble or any kind of stone, is made by mixing 20 parts of litharge and 1 part of freshly burned lime in fine dry powder. This is made into a putty by linseed oil. It sets in a few hours, having the appearance of light stone.

To Make Sailcloth Impervious to Water, and yet Pliant and Durable.—Grind 6 lbs. English ochre with boiled oil, and add 1 lb. of black paint, which mixture forms an indifferent black. An ounce of yellow soap, dissolved by heat in half a pint of water, is mixed while hot with the paint. This composition is laid upon dry canvas as stiff as can conveniently be done with the brush. Two days after a second coat of ochre and black paint (without any soap) is laid on, and, allowing this coat time to dry, the canvas is finished with a coat of any desired color. After three days it does not stick together when folded up. This is the formula used in the British navy yards, and it has given excellent results. We have seen a portable boat made of canvas prepared in this way and stretched on a skeleton frame.

Harmless Pharoah's Serpents.—Many of our readers have seen, and no doubt been amused with the little balls sold as "eggs of Pharoah's serpents," which, when ignited, turn into a long twisted rod of fused ashes, having a striking resemblance to a snake. Unfortunately the materials of which they are made are highly poisonous, and the fumes, being mercurial, are also dangerous. The following mixture is nearly as good, can be had anywhere, and is quite free from danger: Mix intimately together two parts of bichromate of potassa, one part of nitrate of potassa, and three parts of white sugar. This mixture should be pressed in paper or tinfoil cones, and, if intended to be kept for any length of time, the paper should be varnished over with sandarac varnish. A small quantity of balsam of Peru may be added to perfume the mixture, so as to cause its combustion to be attended with a pleasant odor. The greenish-colored very porous mass, which assumes the serpent shape, is a mixture of carbonate of potassa, oxide of chromium, carbon, and a small quantity of neutral chromate of potassa. We have tried this recipe with very satisfactory results.

Inquiries and Answers.

Inquiries.

38. What is the composition used for making electrotype moulds? How are the moulds taken from the type? A. W. P.

39. Can any of your readers furnish directions for dissecting the abdomen and internal organs of the spider? Taylor, formerly State Entomologist of Georgia, speaks of a mould being taken by dropping melted suet therein, but does not give process. ENTOMOLOGIST.

Answers.

40. In answer to B. G. P. (36), the acid used in engraving upon steel is nitric (poison). The best method of applying it is as follows: Clean the part to be engraved upon, then pour over this a thin layer of melted wax; allow it to harden, and scratch on the wax the name or device with a pin, so that wherever the pin has been the surface of the object to be engraved is free from wax; now with a little stick, bruised so as to look like a little brush, apply the acid over the wax, allowing it to eat the iron or steel in the lines made by the wax; ten minutes will be sufficient to engrave the work; then wash and remove the wax. J. C.

41. In answer to B. G. P. (36), first clean the blade of the knife thoroughly, and then apply a coating of beeswax to the blade, being careful to get the whole surface covered. Then cut the name in the wax, being careful to remove the wax from the blade wherever the etching is required, after which apply strong muriatic acid for a few seconds, and then wash thoroughly in water. SUBSCRIBER.

EXCHANGES.

In this column yearly subscribers who may wish to *exchange* tools, apparatus, books, or the products of their skill, can state what they have to offer and what they want, *without charge*. Buying and selling must, of course, be carried on in the advertising columns.

Hamilton, Up. Held. and Carboniferous fossils; also eastern minerals, to exchange for fossils, minerals, shells, or Indian relics; list of duplicates and desiderata sent upon application. B. H. Wright, Penn Yan, N. Y.

To exchange, 2-column adding machine, American Manual of Phonography, collection of foreign stamps and Confed. money, books, and files of illustrated and literary papers, for printing material or press; or for spy or opera glass. J. N. Huston, Box 108, Chase City, Va.

Minerals, fossils, Indian relics, shells, woods, fossil woods, skulls, etc., to exchange for type, sea shells, fossils, foreign coins and stamps. Frank M. Farrell, Box 37, Cobden, Ill.

Great variety of good wood cuts to exchange for good compound microscope, in good condition, of at least 200 diameters. Austin Cravath, Whitewater, Wis.

Bohn's first lessons on Geology, Mineralogy and Fossil Botany, and pair of American Club Skates, given in exchange for a German silver fife and instruction book. Thos. F. Sheridan, Bridgeport, Ct.

Gold watch (cost $150) in exchange for a good microscope. E. W., Box 4875, New York.

Asmall steam engine in good order, cost $1.50, for a dark (bulls-eye) lantern. Geo. H. Umbach, 139 Ross street, Brooklyn, N. Y.

Wanted, a set of wood engraver's tools; Spencer's Psychology, two volumes, given in exchange; also other books for exchange. T. S. Price, Slack's Cañon, Monterey Co., Cal.

Wanted, small turning lathe about 1½ by 12 ins.; state what is wanted in exchange. D. Abrahams, 195 East Broadway, New York.

Wanted, back numbers of the "American Naturalist;" will give "Harper's" or "Scribner's" monthly. —— Hulbert, 131 West Fifty-third street, New York.

Wanted, a 5 by 8 stereoscopic camera box; Fleetwood scroll saw, nearly new in exchange. L. L. Roberts, 1,203 Arch street, Philadelphia, Pa.

Wanted, good microscope and Vols. I and II of "American Journal of Microscopy, or thorough works on botany; thorough instruction in shorthand, by mail, in exchange. T. S. Price, King's River, Cal.

A collection of postage stamps for small cannon or small printing press; will pay difference. C. L. Hackett, lock box 2,210, Roanoke, Ind.

To exchange a good magic lantern, painted slides, cost $8, for a music box of same price, in good order. L. D. Snook, Barrington, Yates Co., N. Y.

McAllister's Household microscope and American Agriculturist microscope, for small 5 or 6 inch turning lathe, or offers. J. Frank Weaver, Brooklyn, Conn.

Graham's Handbook, Synopsis, and 1st and 2d Readers Standard Phonography; tools or advanced scientific books preferred in exchange. E. H. Bidwell, Vineland, N. J.

Complete outfit for stamping key checks, worth $10, in exchange for practical receipt books, or bracket saw with lathe and drill attachment. John Whitty, Jr., Polloksville, N. C.

Woodward's Hospital Microscope wanted in exchange for chemical scales and weights; difference in cash. J. Siler, 1,242 Broadway, St. Louis, Mo.

For exchange, an entire printing outfit, cost $50; state what you have to exchange. F. R. Miller, 750 East Fourth street, South Boston, Mass.

Good $50 job printing press, in perfect order, for a scroll and circular saw, or scroll saw alone; saw must be in good order. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, foot power scroll saw, lathe, or both combined, or good microscope, for minerals, books on plant culture, Art Journal in parts, or cancelled postage and revenue stamps. D. S. Kimball, 48 Exchange Place, New York.

Wanted, small steam engine and boiler of from 1 to 2 horse-power; state what is wanted in exchange. Address Jno. McElvery, Flatbush, L. I.

Wanted, telegraphic and mathematical instruments; Pitman's Phonography in exchange; also thorough instruction in same by mail. F. S. P., King's River, Fresno County, Cal.

Wanted, a copy of Holtzapfel's "Mechanical Manipulation." State what is wanted in exchange. E. W., Box 4875, New York.

Specimens of the marbles, granites and minerals of Vermont, in exchange for Western minerals, or good fossils; minerals and fossil woods from the far West specially desired. Dr. H. A. Cutting, State Geologist, Lunenburgh, Essex County, Vt.

Drawn and engraved by A. W. Roberts.

See page 137.

ACORN BARNACLES.

The Young Scientist

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. I. NEW YORK, NOVEMBER, 1878. No. 11.

A Curious Experience with Acorn Barnacles.

SOW often it happens that just when we think we have made ourselves acquainted with the habits of some grotesque little creature, it will turn and play us an unexpected prank, and often after years of delightful study of our aquaria, we discover some strange development in animal or vegetable life which sets at naught our keenest scrutiny, and upsets all our previous conclusions.

Not the least novel of my experiences was the finding, at Maspeth bridge, which spans an arm of Newtown Creek, thousands of full-grown acorn barnacles (*Balanus balanoides*) attached to strips of oilcloth. The latter were waste pieces from an oilcloth factory; they had been thrown into the creek and had become entangled amongst timbers and rocks. The strips were encrusted on both sides with barnacles so thickly in places that the oilcloth was not visible. Eager to secure a good quantity of these little creatures, so strangely fastened, I took away some twenty yards for my own and friends' tanks, and decorated one of my largest tanks in festoons. The effect, however, was neither natural nor pleasing; I therefore determined to detach them, and if possible invent a means of fastening them to some of the numerous rocks contained in the tank. The oilcloth was waterlogged and partially decayed, so that the barnacles came off readily. I made a cement of two-thirds beeswax, nearly one-third resin, and the rest Canada balsam. I then selected some of the flattest stones and slightly warmed them in an oven. I then placed small lumps of the cement on the warm stones, and pressed the barnacles on the warm cement, causing them to adhere with great firmness; the barnacles having been previously well dried in the open air (they can be kept with safety in the open air forty-eight hours). Parts of the cement were visible here and there, and were unsightly: to cover this defect I attached pieces of serpula, and dead buccinums, and small pyrulas.

A quantity of barnacles remaining still unused, suggested further designs, and I procured some long and short cone-shaped pieces of pumice stone, that resembled stalactites, and covered them with barnacles and algæ. In floating these on the surface, my tank had the appearance of a grotto, the effect of form and light and shade being quite novel. The inquisitive "shrimp" (*Palamentes vulgaris*), and quaint little hermit crabs (*Eupagurus longicarpus*), were soon scrambling over the rocks, cleaning the barnacles to immaculate whiteness. To support this increase of animal life, more oxygen was necessary, and more ulva (*Ulva latissima*) was added.

The barnacles did not feel at home immediately, and the little fairy-like hands were not at work for two days. Then the reaching and grasping began, and so rapidly did they devour the minute animal and vegetable life contained in the water that at the end of a day the water was as clear as crystal, and of a light blue color.

Suddenly, one day, a piece of pumice stone began to revolve, and my first thought was that a prawn or hermit crab was somewhere at work on it; then it seemed as if, from some unknown cause, an imperceptible current of water caused it to turn; but I was finally convinced that I was in error. I took the piece of pumice out overnight, and, assisted by a scientific friend, made a more thorough examination. Placing the stone in the tank next morning, it remained motionless, and I concluded that the mysterious power had departed or was destroyed.

The clearness of the water, and inactivity of the barnacles suggested "feeding time," so I ground three small oysters into a paste, diluted with sea water, and dropped it slowly into the tank. Instantly all the barnacles appeared in motion, and three pieces of pumice stone began revolving rapidly.

The mystery of the moving stone was plain; these three pieces were of nearly perfect cone-shape, and well balanced in the water. The barnacles had been cemented on the cones with their cirrhi, or hands, nearly all pointing one way, so that when feeding they struck the water with their rapidly moving hands, causing the cones to rotate.

I determined to mystify some of my scientific friends over this new motor, so preparing a carefully balanced and turned cone, I cemented the barnacles in nearly concentric circles, with their cirrhi pointing one way. At the top of the cone I dug out a small reservoir, and from this I channeled four gutters extending to the circumference of the base of the cone. In this reservoir I placed a quantity of diluted oyster paste, which slowly worked its way down the gutters and dripped into the water, causing the barnacles to work rapidly. To hide away the reservoir and oyster paste, I draped ulva over the base and part way down the sides, also using small fronds and pieces of *sertularia argentia*, *delesseria*, *enteromorpha* and *chondrus crispus*. All combined gave to the cone the effect of a beautiful mass of marine life.

Another curious fact about this pumice stone cone was that during one very cold night the surface water in the tanks froze over, the low temperature of the water causing the air contained in the pores of the pumice to contract. This allowed the water to enter the pores of the stone, causing it to become heavier than the water, and sink to the bottom of the tank. When the temperature of the water rose again, after the sun had shone on it for a few hours, the air in the stone expanded and floated it up again.

This moving stone was always a source of interest and mystery to my friends. The barnacles lived over a year, slowly increasing in numbers. A. W. Roberts.

—The latest novelty is a "barometer handkerchief." The design printed on it represents a man with an umbrella. In fine weather the umbrella is blue, in changeable weather gray, and in rainy weather white. The secret lies in printing this design in chloride of cobalt; but the first washing removes this sensitive chemical, and destroys the barometric properties.

Lessons in Magic.

THERE is a wonderful fascination about Conjuring, or "Magic," as it is commonly called. Old as well as young succumb to it, and I have yet to meet with any one who, having become at all proficient as a conjurer, ever gave it up entirely.

Within the past few years, very many amateur magicians have appeared, and as there are still hosts of other folks anxious to acquire a knowledge of the "mystic art," I propose in this and following numbers of the YOUNG SCIENTIST to give a course of simple "Lessons in Magic," which I trust I shall be able to make clear to all.

I shall endeavor to avoid as far as possible those tricks that require great manipulation, but as no one can ever hope to become any sort of a magician without a knowledge of *Palming*, I shall begin with an explanation of that most necessary rudiment.

To *palm* a coin, ball, or other article, is to hold it concealed in the palm of the hand, and yet leave the hand in such a natural position that the lookers-on will not suspect that it contains anything. Simple as this appears when done by an expert, it requires no little practice to become perfect in it.

Anything, from a gold dollar to an orange, may be *palmed;* but for a beginner, a silver half-dollar is, from its size, the best to practice on.

Take, then, a half-dollar between the tips of the thumb and fore-finger, and, with the aid of the third finger, slide it along the thumb until it reaches the lower part of the fleshy portion; then, by bringing the thumb around a trifle, toward the palm, the coin will be held by the ball of the thumb on one side, and the palm of the hand on the other, as shown in the accompanying illustration, Fig. 1.

There are several other modes of palming, but this is the most useful, and, for the present, it will suffice.

Palming constitutes the stock-in-trade of some of the best conjurers, and by its aid many wonderful effects may be produced, as, for instance: A coin has been borrowed

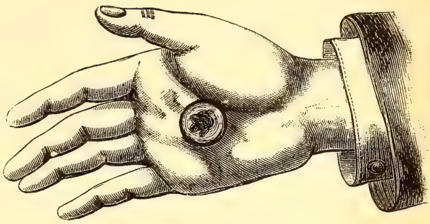

Fig. 1.

for a trick, and the performer hands it to the owner as if to return it. Just as the hand is extended to take it, Mr. Conjurer palms it, and it has disappeared. Some of the audience will imagine it has dropped to the floor, but, to their astonishment, the performer approaches one of their number, and, remarking that "It's really too bad of you, Sir, to play such jokes," apparently takes the missing piece from his beard, hair, or other part of his person. This he does by merely dropping the coin from his palm to the ends of his fingers at the moment that they touch the spot from whence he wishes to take it.

Supposing the student in legerdemain to have practiced *palming* until able to do it well and imperceptibly, he may now pass to a "stage trick," and I will select for this purpose one of the best known to the profession.

The Touch of Midas.—This is a rather fanciful title for what is more generally styled "Catching Money in the Air." The performer borrows a hat, after allowing the audience to satisfy themselves that he has nothing concealed about his arms.

Holding the hat in his left hand, he begins his search for money. He creeps stealthily around the stage, until suddenly, with an exultant cry, he springs forward and catches a coin. He continues picking up money everywhere—in the air, from his own person and from the audience; he shakes it from a lady's handkerchief, and

takes it from a gentleman's beard; everywhere he goes, like another Midas, gold comes at his touch, until at last, tired out, he empties the hat, which he has used as a receptacle for his wealth, before the eyes of the audience, that they may see the treasure he has gathered in.

How is this done? When the performer first goes among the audience both hands are closed, and both contain money; the left hand is filled, and the right holds one piece. In order that the audience may not suspect anything, the tips of the left hand fingers grasp the edge of the lappel of the coat, whilst the right holds his "wand," a short stick, about fifteen inches long, and five-eighths of an inch in diameter, and tipped at the ends with ivory.

Holding the wand in the right hand, the performer requests some gentleman to lend him a hat, and as he receives it, which he does with his right hand, he passes it to his left, which he places inside of it, the thumb only coming outside the rim. The money is now in the hat, and extending his arms, he begs that his sleeves shall be examined. No one suspects the hand, at least I have never heard a word that would lead me to suppose they did. When the examination is over, the performer returns to the stage, and, as he goes to it, throws his "wand" before him to rid himself of it, and at the same moment allows the coin, which has been heretofore concealed in his hand, to drop into his sleeve. Arriving at his stage, he turns his hand to the audience, and shows it is empty. This movement tends greatly to mystify the audience, who, being convinced that neither the sleeve nor the hand contain anything, are at a loss to know where the money comes from. The performer begins his search, and after one or two unsuccessful efforts at catching money "on the wing," he apparently drops his hand despairingly at his side, *and the coin which is in the sleeve falls into his palm*, where he holds it concealed. Now he may commence catching money in earnest. He grasps at the air, and showing between his fingers the coin which he has held *palmed*, the audience suppose he has just caught it. He pretends to throw it into the hat, which is held by the left hand, but in fact *palms* it again, and lets one of the pieces which are in the left hand, drop into the hat. In this way he proceeds, catching, showing and palming the single coin of the right hand, and dropping into the hat, one by one, the coins from the left. When three or four coins only remain in the hand that holds the hat, he again "catches" a coin with the right hand, and this time really throws it into the hat, and, holding up the hand, says, "You see there is nothing concealed here, *nor here.*" As he says this, he passes the hat from the left to the right hand, and placing the fingers of the right hand inside the hat, with the thumb remaining outside, takes the few coins that are left. He holds up the left hand, that all may see it is empty, and then passes the hat back to it, retaining the coins, however, in the right hand, with which he palms them. He then begins again to "catch" the money, letting one coin at a time drop from his palm to the ends of his fingers, and as he "catches" it holds it up to view, and then throws it into the hat, in such a way that all may see him do it. By this little feint, he makes his audience believe that he threw all the coins in, and does away with any suspicion they may have had to the contrary. He now turns the money out of the hat on to a plate, and returns the hat, if he does not need it for another trick.

To be continued.

Wood-Carving—II.

SHARPENING TOOLS.

THE first thing to do is to learn to sharpen your tools. They generally come ready ground from the store, and merely require to be sharpened on an oil-stone. The oil-stone should be set in a block of wood, and fitted with a cover, so as to protect it from dust and dirt, and give it a broad, firm basis, on which to stand. A small particle of hard grit falling on the

stone and remaining there while the tool is being sharpened, will often seriously injure a fine tool, and great care is therefore required in this respect. To keep an oil-stone in good condition, it must be kept clean and free from old gummed-up oil. When the oil becomes thick and gummy, the tool slides over it without being ground away, and your labor is lost. The best kind of oil, in our opinion, is good sweet oil. Some recommend kerosene, but we have found that it hardens the stone and injures it. It is also necessary that the stone for sharpening chisels, etc., should be kept perfectly flat. When it becomes irregular, the best method of making it true is to grind it down upon some flat gritty stone, with water, and afterwards smooth it off by rubbing it over with a flat slate charged with very fine emery. After having cleansed off the stone carefully, put a little oil on it, take one of your chisels, the handle in your right hand, put it on the stone, and holding it at the angle at which it has been ground, place the fingers of the left hand on the face, and with a moderate pressure rub it steadily backwards and forwards, looking at it frequently to see if you do not get it down too much, and make what is called a wire edge. When it is sharp enough, raise your right hand a little, give the edge of the chisel a semi-circular forward sweep or two on the stone; then turn the face down, give it two rubs with a semi-circular forward sweep, and your chisel will be sharp. If you should get a wire edge, draw the tool over the edge of a table or board, and it will come off. If this does not remove it, stick the tool upright on the table, and bend it backwards and forwards; then put it on the stone again, giving it, with the hand raised, the semi-circular sweep we have before described. Sharpen your gouges in the same way, only you must keep turning your hand as you rub to and fro, so that each part of the edge of the gouge may come in contact with the stone. We sharpen our gouges in a manner different from most people. We hold the gouge across the stone, giving it a rocking motion by turns of the wrist, as we push it up and down the stone. To explain: Bring the gouge close to you, holding it across your body; put the further corner of the gouge down on the stone, push from you, and at the same time turn your wrist, so that the upper or nearest corner comes down on the stone; drawing it back, reverse the motion, and in this way every part of the edge of the gouge will be equally ground by the stone. We have found this by far the best plan, as the edge does not get rubbed away more in one place than in another. Then, as you can not sharpen the face, which is hollow, on the oil stone, take the slip between the finger and thumb of your right hand, and holding the gouge firmly in the left, sharpen the inside of the tool. Take care not to rub away too much of the face of your tools, for it is the hardest and most precious part.

The V tool is the most difficult of all to sharpen. This must be done with the flat side of the slip, and take care that it is not more rubbed on one side than the other. It will require considerable practice and much patience to learn to sharpen this tool well; but in this, as in all other things, remember the old Spanish proverb: "With patience and perseverance the mulberry leaf becomes a silk gown." The final touches, which give to the tools the last degree of sharpness and smoothness of edge, are given on a piece of stout leather, about an inch and a half wide and eight inches long, glued to a board, and rubbed over with the very finest emery paste, which is emery made into a stiff paste with tallow. The emery must be perfectly free from grit; and, to obtain it in this condition, you must get some of the very finest flour of emery and mix it with water in a tall jar, such as a good-sized fruit jar. After stirring it up vigorously, allow it to settle for say a minute; pour off the liquid into another vessel, and allow the fine powder that remains in it to settle completely. Pour off the liquid, dry the powder, and keep it for use. The strop should be kept carefully covered, to protect it from dust; and, if the emery be good, it will impart to your tools an edge

as keen as that of a razor. The leather should be hard, firm, and of even texture. Some persons recommend soft buff-leather; but this, we think, is a mistake, and we know that it does not sharpen nearly so well as a piece of hard leather that will not yield to the tool; for it is easily seen that if the leather is soft and yields, it will curl up behind as the tool passes on, and will round off the edge instead of leaving it a true bevel.

To be continued.

How to Study Entomology.

BY F. C. SMITH.

V.

Continued from page 129.

IF a chrysalis be examined closely, all the principal parts of the future moth or butterfly may easily be discerned. The wings will be seen folded around and under the thorax; the head, eyes, and antennæ are very prominent, and the legs may be distinguished neatly folded under and between the wings, the whole a beautiful illustration of Nature's universal economy of space. The length of time the insect remains in the pupa state varies with the species from three or four weeks to seven years. Many varieties, however, may be forced by a high temperature. The wing of a moth or butterfly just emerged from the chrysalis is really full size, though in appearance it is very diminutive. The fact of its being folded in so small a compass has led to many a dispute among entomologists. A little patience and careful attention during the hatching season will, however, convince the most incredulous. Usually, in three or four hours after emerging, the insect is in a perfect state to kill.

The order *Lepidoptera* is classed at present into two divisions—the butterfly with clubbed antennæ and four distinctly visible wings when at rest, and the moth with feathered and pointed antennæ and a much larger body in proportion to the wings. The secondary wings of the moth are usually covered by the primaries when in a state of rest. The silk of commerce is obtained from the cocoon of the *Bombyx mori*, the moth of which is small and insignificant in appearance. The *Attacus cecropia* spins a cocoon of strong silk, but it has never yet been unwound to the writer's knowledge. No doubt it will some time be used in the arts, as from it could be made the strongest of paper.

To those who make *Lepidoptera* a special study, the "Synopsis of the Described Lepidoptera of North America," by John G. Morris, will prove invaluable.

The *Coleoptera* have four wings, two only being used in flying. The anterior wings are simply sheaths or shells, under which are folded the secondaries for protection when the insect is at rest. The mouth is provided with mandibles, jaws and lips, and the food is masticated. This insect undergoes the larva, pupa and perfect state, and the larvæ being found in almost every soil, is easy of access to the student. A great number live in the excrement of animals, others attack the roots of trees, vegetables, etc., also bark, wood, leaves and fruits.

With even a fair microscope the *Coleoptera* offers a wide field of investigation, as the insects of this order are easy of dissection, and the parts readily accessible.

To be continued.

Home-made Hanging Baskets—I.

(*Illustrated by A. W. Roberts.*)

THE cool nights of October warned me that the frost-king would soon be here, chilling and killing my floral pets, who had bloomed out their beautiful natures all summer. To leave them now to perish seemed like heartlessness.

Having neither pots nor window boxes, I made a grand collection of all such ancient and infirm butter tubs, wash boilers, tin pans and fruit cans, as are to be found about an old homestead. In these I seasoned my plants down till I could procure more fitting receptacles for them. I found the prices of window boxes and hanging

baskets at the largest dealers greatly above the condition of my pocket-book, and as for flower-pots, there is something about their artificial shape, and bricky red look that always produced in me a great desire to cover them over with some material to hide their offending color and form.

How to do it? that's the question. I made my first experiment on a cracked and partly broken flower pot, first scouring it with sand and water, then applying a thin rough coating of plaster of paris, previously colored with a mixture of ultramarine blue and one of the dark chrome yellows, which gave me a dark green of considerable body. After this coat dried, I applied a second rough coating of plaster mixed with burnt sienna and rose pink, which made a rich warm brown. The pot must be moist when the plaster is laid on or it will not adhere.

Fig. 1.

This second coat, as shown in Fig. 1, requires a little practice in laying it on in the serpentine and angular forms. For this purpose I used an old table knife. Mixing a small quantity of plaster at a time with water to the consistency of thick paste, I began laying on the plaster about the rim of the pot, working around the po till I reached the bottom. I then placed the pot on a sheet of oiled or greased paper; this is to prevent the plaster working under the pot, thereby causing it to stand unsteadily. I again laid on more of the plaster, building out the pattern from the bottom of the pot, till it was nearly as large as the rim in circumference. I now had a pot that looked like very deep bas-relief at the base, gradually becoming more shallow at the rim. After the plaster was thoroughly dry, I gave it two coats of boiled linseed oil to bring out the rich colors, and make the plaster tough and impervious to water. To make a hanging basket of this pot, I inserted a greased stick in the drain hole of the pot. To the bottom of the pot, and around the stick, I built more ornamental work in plaster, extending the pot down to a point. I then withdrew the stick, thus leaving a hole through the plaster for drainage. To hang

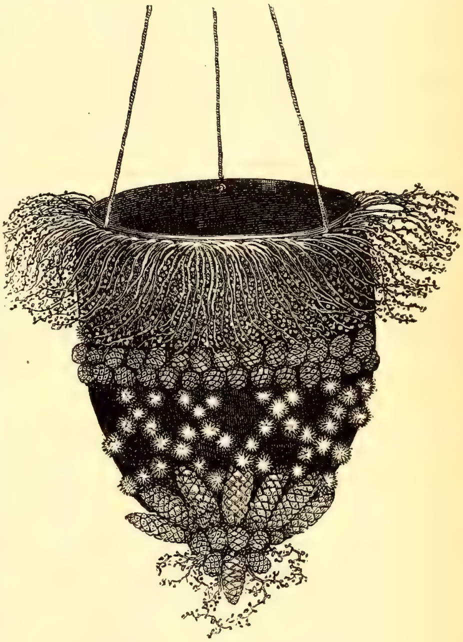

Fig. 2.

this pot, I bored three holes just under the rim; in these holes I fastened nickel plated wire cords (such as are sold by picture frame dealers), bringing the ends together a yard above the pot, and hanging it to an iron hook screwed to the top of the window.

My next attempt was with a cocoanut

shell, as shown in Fig. 2. I sawed off one end of the cocoanut, cleaning out the meat thoroughly; then scraped off the rough fibres with a piece of window glass, and after this I sandpapered it down smooth and varnished it. To the cocoanut I fastened the burrs of the liquid amber tree with a cement of hard asphalt, thickened with lampblack, first grinding the lampblack in asphalt varnish to cause it to mix more readily with the hard asphalt when heated. Around the centre of the nut I fastened a band of pine cones. The bottom I finished off with cones of the fir tree. Along the rim of the nut I bored holes, and into the holes I inserted branches of black alder with the burrs on. I also bored a hole at the bottom for drainage, otherwise the earth in the pot would sour, and the plants die. In this hanging pot I planted young plants of Maurandya, which twined amongst the alder branches. I also planted slips of the so-called German ivy, to twine up the nickel wires.

Microscopy.

What Can be Done with a Cheap Microscope.

SO much has been published of late about the great superiority of the microscopes made by first-class opticians, and the comparative inferiority of the cheaper forms, that there is danger that the owners of the latter may get discouraged, and abandon altogether the use of the microscope, because they cannot afford a Zentmayer Centennial Stand and first-class objectives by Tolles or Spencer. Now, while we yield to none in our appreciation of the work of great microscope makers, and would earnestly advise every one to get as good an instrument as circumstances will allow, we think it may be well to give the owners of cheap instruments a word of advice and encouragement.

By a cheap microscope is meant one costing less than $30. For any sum less than this it is impossible to procure, in the present state of the market, an instrument possessing the qualities and appliances necessary for the performance of anything except the most elementary work, but then, on the other hand, it is astonishing what a wide range of ground is covered by the term "elementary work." If we take the cheapest form, say a common lens of a quarter-inch focus, we will be able to see a great deal that is utterly invisible to the unassisted eye; with a $20 microscope, judiciously selected, we can follow almost all the descriptions and explanations found in the ordinary text books. Let us take a middle ground, and consider the capabilities of such an instrument as may be had for from $10 to $20.

Such a microscope will not enable us to determine disputed points in histology, or to investigate the structure of test objects like the *Podura* scale, or *P. angulatum*. But it will show us clearly and well the various kinds of tissues, and even the cyclosis or so-called circulation of the sap in plants; it will show us the forms of the various kinds of pollen, and the number, situation and form of the stomata or breathing pores of plants; it will even show the more minute forms of plant life—those beautiful desmids and diatoms, which have always been the delight and the admiration of those who use the microscope, and although it will not enable us to see the markings on the more minute diatoms, it will show us their general forms and outlines, and reveal to a diligent and careful observer much of their life-history.

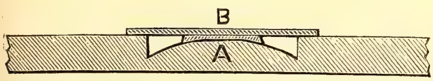
In animal physiology it will show us the peculiar forms of the blood of different animals, and it will show readily that most wonderful and beautiful of all microscopical objects, the circulation of the blood in the foot of the living frog. It will show us the structure of muscular fibre, and the peculiarities of the epithelium which lines the various internal organs. By it we can trace clearly the outlines and structure of many of the lower forms of animal life which

would be otherwise invisible, and we will be thus enabled to assign them their proper place in the great system of classification. By it, too, may be studied the habits and life-history of the majority of the animalcules found in liquids.

That these statements are not exaggerated is shown by the fact that some of the most important discoveries have been made by means of microscopes far inferior to those that can now be had for $20. Indeed, much of the work of the great Ehrenberg was done with a microscope which to-day would not command $25. Therefore, let not the owners of cheap microscopes despair, for the field which is open to them is sufficient to occupy the longest life, and te employ the highest powers.

The Weber Slide.

THERE is no doubt in the minds of those who use the microscope that living objects, whether animal or vegetable, are by far the most interesting, especially to beginners, and a simple and inexpensive means of preserving and exhibiting them has long been a desideratum. The well-known live-box or animalcule cage serves the purpose very well, but it is expensive, and does not entirely prevent the evaporation of the liquid in which the objects are contained. The ordinary concave slide,



THE WEBER SLIDE.

though better than a plain slip of glass, does not fulfil all the requirements, and with such a slide it is difficult to keep the object in focus, except with very low powers.

To obviate these difficulties, Mr. Weber has reversed the form of the cell, and forms his slide as shown in the accompanying engraving, where A is the convex bottom of the cell, and B the thin glass cover—a drop of water being held between them by capillary attraction. When the cover is cemented down by means of a little water-proof cement, the water cannot evaporate, and the whole arrangement forms an air-tight aquarium on a minute scale. The open space forms a chamber which retains a supply of air, and if the animal and vegetable life are properly balanced, life may exist in one of these slides for weeks. Indeed we have been surprised at the length of time that they keep in good condition.

In the engraving, which shows the slide as manufactured by Mr. C. F. Prentice, of this city, the thickness of the slide, etc., is magnified about four times.

Volvox Globator.

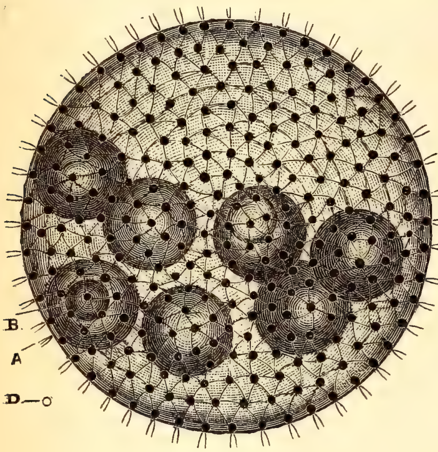
A RECENT English writer tells us that the most popular objects amongst the amateur microscopists of his country are the *Volvox globator* and the *Conochilus*, and there can be no question that they deserve all the attention that has been bestowed upon them. Fortunately they are both found in the ponds of this country, so that we feel certain that our readers who will carefully seek for them will be pretty sure to find them. During the past few years, the life-history of the *Volvox* has been very carefully and thoroughly worked out, and those who desire to study it will find a very excellent article by Prof. Alfred W. Bennett, in a recent number of the *American Journal of Microscopy.* But as this article is very elaborate, we have thought it well to prepare the following simple description for the benefit of our younger readers.

When first discovered by Leeuwenhoek, about two hundred years ago, it was regarded as an animal, and even now the uneducated observer can hardly believe that it is a vegetable. Such it is, however, despite its power of locomotion, and its very peculiar and beautiful form. The reader must bear in mind that there are many minute plants that have the power of moving through the water in which they live—some of them with considerable speed.

The usual appearance of the *Volvox* is very well shown in our engraving. Under a moderate power, it appears as a pale green globe covered with dots, from each of

which proceed two cilia, and it is the motion of these cilia that cause the globes to roll through the water. In the interior of the *Volvox* may be seen from two to twenty smaller globes, and sometimes these small globes contain others still more minute. After a time the small globes escape from the parent globe, and pursue an independent existence, after which the parent dies.

It is not many years since the *Volvox* was considered quite a rarity in this country, and many good microscopists believed that it was not to be found in American waters. The writer has a distinct impression that he



VOLVOX GLOBATOR.

was told by the late Dr. Goadby, who was quite familiar with it in England, and had traveled extensively in this country, that he had never met the *Volvox* in America, and yet Goadby was quite familiar with the microscopic inhabitants of our ponds. At any rate it is but a few years since the writer himself first saw it and published the fact, but since that time it has been frequently discovered in localities in which it was not supposed to have been previously found. It must be remembered, however, that the *Volvox* is very apt to escape the observation of those who are not familiar with it, and yet, like the well-known puzzle pictures, when once seen it is ever afterwards quite obvious when present. Evidence of the truth of this statement is found in the fact that while the ponds around London have always been famous for *Volvox*, Baker, at the time of writing the first edition of his book, "Employment for the Microscope," (1753) had never found them himself, and wrote his description from specimens accidentally found in water sent to him from Yarmouth by a friend.

The *Volvox* is generally found in clear still water, free from such filth as sewage and decaying animal matter. The clear, open spaces amongst water plants are always likely places. We have found it in ponds densely shaded by trees, and also in those that were entirely exposed.

In searching for the *Volvox* and similar organisms, we have found the best instrument to be a clean homœopathic phial of good size—say half an ounce. Such a phial may be fastened to the end of a cane by means of the cheap little device shown on page 131 of "How to Use the Microscope." A "dip" may then be taken from any clear pool, the bottle removed from its holder, wiped dry on the outside, and examined with a half-inch lens. The *Volvox*, if present, will be seen as a pale-green globe, rolling about in the water and having little specks in its inside. In order to cause all the water to pass before the lens, it is well to give the bottle a slight whirl.

Under a power of twenty-five to fifty diameters, such as can be had from any cheap microscope, the *Volvox* presents a most beautiful and interesting appearance. To examine its ultimate structure requires good instruments, but its general form and its beautiful movements may be seen by means of a little French stand costing $2.50.

The Heavens for November.

BY BERLIN H. WRIGHT.

THE computations in the following are made for the meridian of New York city, and are expressed in mean or clock time:

The Superior Planets—How to Find Them, and their Telescopic Appearance and Ephemerides.—Mars is an object of great interest, both to the practical astronomer and the amateur observer. His surface has been more closely studied than that of any other planet, and though 51,000,000 miles distant, the natural divisions of its surface are accurately mapped and named. Thus Herschel Continent, Cassini Land, Hind Peninsula, Phillip's Island, Delure Ocean, Delambert Sea and Arago Strait, are among the natural divisions given in *our* Martial geography.

A telescope of two-inch aperture will give fair views of the continental mark-

ings; and a smaller glass of the snow-capped poles.

At and near quadrature, and for fifty days before and after opposition, Mars presents a gibbous phase, which is easily seen with a telescope having an aperture of two inches.

He is now a morning star, and rises as follows:

1st—5h. 19m., morning.
10th—5h. 13m., morning.
20th—5h. 9m., morning.
30th—5h. 3m., morning.

On the 1st he rises about 6° north of the sunrise point. He is moving eastward among the stars of the constellation *Virgo*, and will be very near the brilliant star, Spica Virginis during the latter part of the month, being 2° 58′ north of it. He will be in conjunction with the moon Nov. 22, being about 6° north.

Jupiter presents the best field for the amateur of all celestial objects, and is one of the easiest to observe. When near opposition, and his maximum northern declination, his brilliancy is not excelled by that of Venus when brightest, which is the only planet which ever exceeds him in brightness.

His four satellites may be seen with a good opera-glass. We have seen it stated that the two outer ones have been seen with the naked eye, but we doubt it. The objects seen must have been small stars in the vicinity of the planet. His moons are always to be seen nearly in a straight line with the planet, extending east and west. Sometimes all four will be on one side, two on each side, or three on one and one on the other. One, two, or even three, may be invisible at once, being eclipsed, occulted, or in the act of making a transit.

An opera-glass will answer to observe an eclipse or occultation with, but it requires a telescope of two-inch aperture to see the shadow of a satellite make a transit across the planet's disc, and a three-inch instrument to see the satellite itself while in transit. The inner two transit and are occulted by the planet at each revolution around Jupiter; the third may occasionally pass very close to his northern or southern limb, while the fourth is frequently seen during an entire revolution.

Jupiter is an evening star, and sets as follows:

1st—10h. 8m., evening.
10th—9h. 38m., evening.
20th—9h. 6m., evening.
30th—8h. 35m., evening.

He is moving eastward very near the eastern limit of the constellation Sagittarius, and will be very near the moon on the 28th, being about the moon's apparent diameter south of her.

The visible phenomena of his satellites for November are:

Satellite I, begins a transit at Jupiter's eastern limb, Nov. 1, 7h. 11m., evening; is followed by its shadow at 8h., 29m., evening, and emerges at 9h. 31m., evening. Begins transits also at 9h. 9m., evening of 9th; and at 7h. 37m., evening of 24th; and completes one at 7h. 57m., evening of 17th. Reappears from an eclipse at the east of the planet (erect vision *always* understood; for an inverting eye-piece reverse the directions) at 8h. 8m., evening of 2d; and at 6h. 27m., evening of 18th. Disappears at the western limb, being occulted, at 6h. 29m., evening of 9th, and at 8h, 27m., evening of 16th.

Satellite II disappears, being occulted, at 8h. 48m., evening of 5th; and at 6h. 25m., evening of 30th. Completes a transit at western limb at 6h. 40m., evening of 7th; begins one at 6h. 35m., evening of 14th, and reappears from an eclipse at 6h. 16m., evening of 16th.

Satellite III. Shadow begins a transit at 6h. 27m. evening of 10th, and reappears from an eclipse at 8h. 5m., evening of 28th.

Satellite IV disappears in an eclipse at 6h. 33m., evening of 7th.

At present all eclipses take place to the *east* of the planet.

For fear of making this article too long, we will simply give the ephemerides of the remaining planets, leaving further remarks until next month.

Saturn is an evening star, and passes the meridian as follows:

1st—9h. 7m., evening.
10th—8h. 31m., evening.
20th—7h. 50m., evening.
30th—7h. 11m., evening.

He is moving westward at the eastern extremity of the constellation Aquarius, being 3° south of the earth's path, and very nearly on the prime meridian of the heavens, from which right ascension is reckoned eastward. He will be near the moon on the 5th, being 7° south.

Uranus rises as follows:

1st—1h. 2m., morning.
20th—11h. 46m., evening.
30th—11h. 7m., evening.

Neptune passes the meridian as follows:

1st—11h. 41m., evening.
15th—10h. 44m., evening.
30th—9h. 44m., evening.

Penn Yan, N. Y.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

TERMS—Fifty Cents per year. ☞ Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers 12 cents extra.

TO ADVERTISERS.

The YOUNG SCIENTIST has been received with so much favor that its circulation is already greater than that of any other monthly Scientific or Mechanical journal published in the city of New York, with the exception of the *Popular Science Monthly*. It goes into the best families, and has their confidence. NO CLAP-TRAP ADVERTISEMENTS, OR ADVERTISEMENTS OF PATENT MEDICINES RECEIVED AT ANY PRICE.

ADVERTISING RATES—30 cents per line, nonpareil measure.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, etc., see PROSPECTUS.

Our Trial Trip.

IN offering four numbers as a trial trip for 15 cents, our object is to give to those who are interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. Our rule is to send the four numbers at once, and the numbers that are sent vary from month to month, being always the last four that have been issued. As we keep no book accounts of these small transactions, those who remit the remainder of the yearly subscription are requested to state what numbers have been previously sent.

A Liberal Offer.

AS an acknowledgment of past liberality on their part, and an incentive to future efforts on our behalf, we shall give his own copy for 1879 free to every subscriber who is now on our books and who will send us the names of two *new* subscribers and $1.00. That is to say, we will, to each of our present subscribers, give three copies for one dollar.

Please Renew.

THE next issue of the YOUNG SCIENTIST is the last for this year. With it we complete the volume for 1878, and on looking over the matter which we have given and which will appear in the next issue, we feel that we have kept all the promises which we made to our young friends. Next year, however, we hope to greatly improve the journal. Each number will contain not less than sixteen pages of reading matter, and we have been enabled to add very considerably to our list of contributors.

The December number will contain a title page and a very full index, so that the volume will be in good shape for binding. We have made arrangements to bind them neatly and cheaply. For 35 cents we will bind the volumes in cloth with neat gilt title stamped on the back. The postage on the volume will be ten cents, which must be added when sent by mail.

As this is our busy season, we would ask our subscribers to renew promptly. As it does not pay to incur expense in collecting such small sums we shall conclude that those who do not remit do not want the journal, and their names will be struck from our list.

Laboratory & Workshop

Sympathetic or Secret Ink.

Aside from any practical purposes to which they may be put, sympathetic inks form some very interesting and curious experiments. Thus, if we write on paper with a cheap solution of acetate of lead (sugar of lead), and then either dip the paper in a solution of sulphuret of ammonia, or sponge it with that liquid, the letters will appear of a dark brown. To those who see this for the first time, the effect is very curious. Unfortunately, however, all salts of lead become black when exposed for some time to the air, and therefore they cannot be used for secret correspondence. Salts of iron, prussiate of potash, and several other salts which would make excellent secret inks, are also colored by exposure to the air, and cannot be used. Indeed none of the sym-

pathetic inks ordinarily used can be relied upon as a safe means for carrying on a secret correspondence, from the fact that none of them will bear exposure to a degree of heat just sufficient to scorch the paper.

The term sympathetic ink is applied to any liquid which is used to write letters which remain invisible until the writing has been exposed to heat, to some peculiar vapor, or to some suitable solution. Of those which are brought out by the use of a chemical liquid, the best is a weak solution of starch. This is invisible under ordinary circumstances, but becomes quite distinct when washed with a solution of iodine. Writing that is invisible until exposed to heat may be made with milk, lemon juice, onion juice, etc.

In using a sympathetic or secret ink, it is always necessary to write some unimportant matter on the paper or postal card, and between the lines write with the secret ink. If this method of correspondence were used for anything but an interesting experiment, however, it would not be difficult to find a means by which, after writing with the secret ink, unimportant matter might be written with common ink directly over the first writing, and then, by means of a suitable fluid, the last writing might be washed away, and the first writing brought out.

Imitation Ground Glass that Steam will not Destroy.

Put a piece of putty in muslin, twist the fabric tight, and tie it into the shape of a pad; well clean the glass first, and then putty it all over. The putty will exude sufficiently through the muslin to render the stain opaque. Let it dry hard, and then varnish. If a pattern is required, cut it out in paper as a stencil; place it so as not to slip, and proceed as above, removing the stencil when finished. If there should be any objection to the existence of the clear spaces, cover with slightly opaque varnish. In this way very neat and cheap signs may be painted on glass doors.

Glass Working.

Glass is usually brought into shape by being moulded or blown. There are a few other operations, however, which are constantly needed by the amateur, and which we will describe.

For cutting flat glass, such as window panes, and for cutting rounds or ovals out of flat glass, the diamond is the best tool; and, if the operator has no diamond it will always pay to carry the job to a glazier rather than waste time and make a poor job by other and inferior means. When, however, it is required to cut off a very little from a circle or oval, the diamond is not available, except in very skilful hands. In this case a pair of pliers softened by heating, or very dull scissors, is the best tool, and the cutting is best performed under water. A little practice will enable the operator to shape a small round or oval with great rapidity, ease and precision. When bottles or flasks are to be cut, the diamond is still the best tool in skilful hands; but ordinary operators will succeed best with pastilles, or a red hot poker with a pointed end. We prefer the latter, as being the most easily obtained and the most efficient; and we have never found any difficulty in cutting off broken flasks so as to make dishes, or to carry a cut spirally round a long bottle so to cut it into the form of a cork-screw. And, by the way, when so cut, glass exhibits considerable elasticity, and the spiral may be elongated like a ringlet. The process is very simple. The line of the cut should be marked by chalk, or by pasting a thin strip of paper alongside of it; then make a file mark to commence the cut; apply the hot iron and a crack will start; and this crack will follow the iron wherever we choose to lead it. In this way jars are easily made out of old bottles, and broken vessels of different kinds may be cut up into new forms. Flat glass may also be cut into the most intricate and elegant forms. The red hot iron is far superior to strings wet with turpentine, friction, etc.

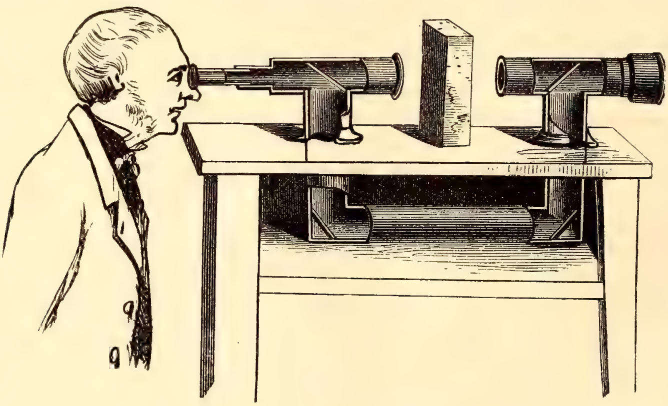
For drilling holes in glass, a common steel drill, well made and well tempered, is the best tool. The steel should be forged at a low temperature, so as to be sure not to burn it, and then tempered as hard as possible in a bath of salt water that has been well boiled. Such a drill will go through glass very rapidly if kept well moistened with turpentine in which some camphor has been dissolved. Dilute sulphuric acid is equally good, if not better. It is stated, that at Berlin, glass castings for pump barrels, etc., are drilled, planed and bored, like iron ones, and in the same lathes and machines, by the aid of sulphuric acid. A little practice with these different plans will enable the operator to cut and work glass as easily as brass or iron.

Black diamonds are now so easily procured,

that they are the best tools for turning, planing or boring glass where much work is to be done. With a good diamond a skilful worker can turn a lens out of a piece of flat glass in a few seconds, so that it will be very near the right shape.—*Amateur's Handbook.*

Looking Through a Brick.

A very common exhibition by street showmen, and one which never fails to excite surprise, is the apparatus by which a person is apparently enabled to look through a brick. Mounted on a simple-looking stand are a couple of tubes which look like a telescope cut in two in the middle. Looking through this telescope, we are not surprised, of course, when we see clearly the people, buildings, trees, etc., beyond it, but this natural expectation is turned into the most startled surprise when it is found that the view of these objects is not cut off by placing a common brick between the two parts of the telescope and directly in the apparent line of vision.



LOOKING THROUGH A BRICK.

In truth, however, the observer looks *round* the brick instead of *through* it, and this he is enabled to do by means of four mirrors ingeniously arranged, as shown in the engraving. As the mirrors and the lower connecting tube are concealed, and the upright tubes supporting the pretended telescope, though hollow, appear to be solid, it is not very easy for those who are not in the secret to discover the trick. Any ingenious boy can easily make this apparatus. The tubes may be made of pasteboard, and the mirrors of pieces of common looking-glass. The telescope should be mounted on a common box, the better to disguise the arrangement. The lid of the box supports the upright tubes, and may form the upper side of the concealed tube. Indeed there is no reason why an apparatus of this kind that would work well, might not be made out of a few old envelope boxes, some bits of looking glass, and a little paper and paste, and if once made it will be a source of constant amusement.

Imitation Terra Cotta.

The following recipe from the *Magazin Pittoresque* will enable our readers to convert plaster casts into excellent imitations of terra cotta ware: The colors required are brick red, lampblack, zinc white, and yellow ochre, all in powder. The object to be treated is first carefully rubbed with "00" sandpaper, so as to remove all roughness of the surface or ridges indicating where the parts of the mold have been joined. The mixed color consists of yellow ochre two parts, brick red two parts, and black one part. These are well rubbed together. Then three parts of zinc white are separately mixed with a little milk to paste. All the ingredients are then combined in a mortar with eight or ten parts of milk, and the resulting mixture is passed through a fine sieve to remove any particles of the white. A soft brush is then used to spread the stain over the object, care being taken to lay it on evenly. After 24 hours' drying, a second coat is applied. When the article is completely dry, rubbing with the fingers will eliminate the brush marks.

Soldering Broken Files.

A writer in the *English Mechanic*, who had broken the only half-round file he had by him, says: "After trying to use the broken end (it was broken about the middle), I was about to give up in despair, when I thought I would try soldering; and, to my surprise, it not only stood while I completed the small job I was then doing, but is in use still, and will stand all the force such a file needs to have applied to it in ordinary use. I used ordinary solder, Baker's soldering fluid, and a Bunsen burner. The temper is injured only at the very joint. Of course I was careful not to heat it more than requisite to melt the solder."

[Baker's soldering fluid is, we presume, a solution of zinc in hydrochloric acid.—Ed.]

To Crystallize Paper and Glass.

The following process is recommended by Professor Bottger: Mix a very concentrated cold solution of salt with dextrine, and by means of a broad, soft brush, lay the thinnest possible coating of the fluid on the surface to be covered. After drying, the surface has a beautiful, bright mother-of-pearl appearance. To make the coating adhere to glass, it is only necessary to varnish it with an alcoholic solution of shellac. The following salts give the finest crystallizations: Sulphate of magnesia, acetate of soda and sulphate of tin. Colored glass thus prepared gives a good effect by transmitted light.

BOOK NOTICES.

Physical Technics; or Practical Instructions for Making Experiments in Physics, and the Construction of Physical Apparatus with the most Limited Means. By Dr. J. Frick. Translated by John D. Easter, Ph. D. Seven hundred and ninety-seven illustrations. Price $3.00. Philadelphia: J. B. Lippincott & Co.

This book is to the experimenter in Natural Philosophy what Faraday's "Chemical Manipulation" was to the chemist. It contains not only minute directions for performing experiments successfully, but very clear instructions for making apparatus and using the ordinary tools. In many respects it is the best work on mechanical manipulation now before the public, and so far as amateurs are concerned, this is certainly true. All the various arts, such as glass-blowing, screw-cutting, soldering, brazing, working with files, planes, etc., are very fully treated. Our readers, old and young, will find it a mine of useful information.

The Amateur's Handbook of Practical Information for the Workshop and the Laboratory: Containing clear and full Directions for Bronzing, Lacquering, Polishing Metal. Staining and Polishing Wood, Soldering, Brazing, Working Steel, Tempering Tools, Case-Hardening, Cutting and Working Glass, Varnishing, Silvering, Gilding, Preparing Skins, Waterproofing, Making Alloys, Fusible Metals, Cements, Glues, etc., etc. Price 10 cents. New York: Industrial Publication Company. 1878.

This is not a mere book of recipes clipped from old journals and encyclopœdias, but a carefully compiled book of instructions for performing those little technical operations which are so frequently required in every-day life, and in the workshop of the amateur. In most of these operations the recipe is but half the battle; when we come to put it in operation we are apt to fail from ignorance of some general principle, or from inattention to some important though apparently trifling detail. In the book before us this defect is avoided, and minute practical directions are given, so that any one may be able to put the recipes in practice. This is specially apparent under such headings as glass-cutting, lacquering, steel working, brazing and soldering, silvering, staining woods, waterproofing, etc.

Current Notes.

To Fix Pencil Marks so they will Not Rub Out.—Take well skimmed milk and dilute with an equal bulk of water. Wash the pencil marks (whether writing or drawing) with this liquid, using a soft camel-hair flat brush, and avoiding all rubbing. Place upon a flat board to dry.

Carrying Water in a Sieve.—The following simple experiment will perhaps interest some of our readers: Take a tumbler and tie over its mouth a piece of bobbinet or other open fabric; immerse it in water, and when partly or entirely full, invert it, and lift it carefully out of the water bottom upwards. The water will not run out, but will remain suspended in the tumbler.

Packing Glass Ware.—Every one has this duty to perform occasionally, and it is well to know how it should be done. The safety of glass articles packed together in a box does not depend so much upon the quantity of packing material used, as upon the fact that no two pieces of glass come into actual contact. In packing plates, a single straw placed between two of them will prevent them from breaking each other. In packing bottles in a case, such as the collecting case of the microscopist, and the test case of the chemist, rubber rings slipped over each, will be found the best and handiest packing material. They have this great advantage that they do not give rise to dust.

To Keep Pipes from Freezing.—The only certain preventive is the removal of the water, and it is worth while to make provision for turning off the water during very severe nights, letting it on during the day time. We must not forget, however, that merely shutting off the water will not answer; the water must be let out of the pipes. To do this a small tap or petcock should be placed just above the main stopcock, or the latter should be made with a vent which allows the water above it to flow out when it is turned off.

Lemon Tree Wood.—A writer in the "Gardener's Monthly" says that when in Rome, a few years ago, he was shown some work made out of the lemon tree that was considered almost as good as if made from box; and he makes the suggestion that a plantation of lemon trees for the wood, to say nothing of the fruit, would be profitable. The lemon tree is generally grown for fruit, but it would no doubt do well from a wood-growing point of view in less favorable climates. The lemon tree ought to do well at the South, and in many parts of California, and as boxwood is becoming quite scarce and expensive, the experiment is worth trying.

Fair of the American Institute.—The large building in which this Fair is held, seems to be better filled than ever this year, and many of the articles on exhibition are of unusual interest. One of the great attractions is the electric light, with which the building is illuminated, thus giving those who desire to see this new mode of lighting an opportunity to do so. One of the most interesting features of the Fair is the machinery in motion, and the various industries, the operations of which are carried on in the building. This makes the Fair one of the most efficient educational agencies in the city, and there is no place to which parents can take their children more profitably than to the American Institute Fair.

Artificial Black Walnut.—A Belgian journal says a new process has been applied to the manufacture of artificial black walnut, by which ordinary wood has imparted to it the appearance of the most beautiful specimens of walnut, adapted to the very finest cabinet work. The wood, first thoroughly dried and warmed, is coated once or twice with a liquid composed of one part by weight of extract of walnut peel, dissolved in six parts of soft water, by heating it to boiling, and stirring. The wood thus treated is, when half dry, brushed with a solution of one part by weight of bichromate of potash in five parts of boiling water, and, after drying thoroughly, is rubbed and polished. The color is thus said to be fixed in the wood to a depth of one or two lines, and, in the case of red beech or alder, for instance, the walnut appearance is most perfect.

A Good Hint for Photographers.—Dr. Thos. Buzzard, who was recently undergoing the usual ordeal in a photographer's gallery, conceived the idea of suggesting some arrangement for relieving the eyes during the time it was necessary to keep them fixed upon a given object. In his own case he found that staring at a certain spot caused his vision to become indistinct, and surrounding objects became lost, as in a thickening mist, whilst as the sitting was prolonged, a feeling of giddiness and even faintness was experienced. The plan he suggested was to draw upon a piece of card, about four inches in diameter, a clock-face, and add the usual Roman figures. This card was fixed about eight feet distant, and when the sitting began he fixed his eyes upon the figure XII, and then upon the I, II, III, and so on all around the clock, shifting his gaze leisurely from one figure to the other. The result was the sitting ended without any sense of strain, and he seemed to have sat without an effort, while the slight change in the direction of vision required did not at all affect the accuracy of the portrait.

Studio Glue.—Every one knows what a nuisance it is to "heat the glue-pot" when some small mend has to be made. And most people also know that all substitutes for glue are more or less failures for wood work of all kinds; and, indeed, for most kinds of soft substances there is no cement that is so thoroughly satisfactory as glue. I have found an exceedingly simple way of using glue for small mends, and for general purposes where but a little is wanted at a time. The simplicity of the matter is so great as almost to need an apology for mentioning it, but its utility is so great that I must make that my excuse for writing about it. This is the method: Put a pinch of Nelson's shredded gelatine into a wide-mouthed bottle; put on it a very little water, and about one-fourth part of glacial acetic acid; put in a well-fitting cork. If the right quantity of water and acid be put, the gelatine will swell up into worm-like pieces, quite elastic, but at the same time, firm enough to be handled comfortably. The acid will make the preparation keep indefinitely. When required for use, take a small fragment of the swelled gelatine, and warm the end of it in the flame of a match or candle; it will immediately "run" into a fine clear glue, which can be applied at once direct to the article to be mended. The thing is done in half a minute, and is, moreover, done well, for the gelatine so treated makes the very best and finest glue that can be had. I have no doubt this plan might be modified by dissolving a trace of chrome alum in the water used for moistening the gelatine, in which case, no doubt, the glue would become insoluble when set. I have not tried this, as, for general purposes, there is no need for subsequent insolubility in glue.—*Photographic News.*

The Young Scientist

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

Vol. I. NEW YORK, DECEMBER, 1878. No. 12.

Masked Christmas Gifts.

OUR small folks having lost all faith in the kindly offices of the little old gentleman who once a year is supposed to fill long stockings and short socks, I determined to have all Christmas presents masked in various articles of food, and in this way bring about a series of surprises and enjoyable mysteries. Strict orders were therefore given to the cook to provide an abundant supply of cold slaw with the oysters, and that pumpkin pie must not be forgotten as part of the Christmas dinner.

After all the big and little folks had retired, I descended into the kitchen to make my first experiment.

Of course Bridget was to be up first in the morning; why not begin with her presents first? So selecting the pumpkin which was purchased for the pies, as a most promising subject for a beginner, a square was cut out from about the stem with a thin and sharp-bladed knife, taking care to bevel the edges inwardly to prevent the piece from falling into the pumpkin when put back again (see Fig. 1). Great care was taken to avoid making false cuts or tearing the skin of the pumpkin. The seeds and pulpy fibre were then removed from the inside, which was rubbed dry with a coarse towel.

Bridget was to have two presents—a string of black beads and cross, supposed to look like real jet, and a silk handkerchief. The beads were done up in several thicknesses of paper, securely tied with string, and labeled "Miss Bridget Lundragun's Christmas," so that there might be no mistake about the ownership. The piece that had been cut out was then put back in its place and securely fastened with entomological pins, as shown in Fig. 1. As the seam and the pin heads showed in places, I rubbed dry flour on the pumpkin, which gave it a "must have fallen into the flour barrel" look. It was then left on the table for Bridget's early attention.

The cabbage was doctored the same way, a piece being cut out where the stalks grew and the inside scooped out with an old

table spoon, the rim of which had previously been ground to a sharp edge. In this was placed the handkerchief, done up in many wrappings of old muslin to prevent the moisture contained in the cabbage from affecting the finish of the fabric, and to

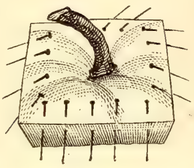


Fig. 1.

protect it from the cutting knife. Brown bread and rolls, and a loaf of either wheat or rye bread had been ordered for breakfast. Ascertaining that all these things were in the house, I visited the baker and duplicated all the above named articles (as those containing the presents would not be fit to be eaten) securely hiding them so that they might be produced when needed. Taking the loaf of brown bread, I made a clean cut half an inch below the top (Fig. 2, dotted line), then scooped out the inside, taking care not to make the walls of the hollow loaf too thin. In this I placed a piece of jewelry bountifully wrapped in cloths to make it fit compactly inside the loaf, and

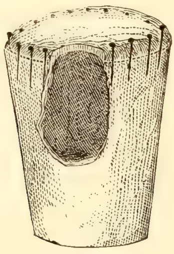

Fig. 2.

prevent anything loose being felt inside. The cloth also protected the jewelry from the knife when the bread was cut. The top of the loaf was fastened in its place with long pins (Fig. 2), and the joint was covered with a brown paste made of crumbs of the bread. The loaf was then placed in the oven for half an hour to thoroughly bake the paste joint.

The rolls were mostly filled with candies, each roll containing a different kind; others held a gold pencil case, a pair of child's kid gloves, etc. The hollowing out of the rolls and sealing up was found to be very easy, being accomplished in this way. From the bottom of each roll I cut out a square piece of crust; with my fingers I removed all the inside crumb, then filling the rolls with candies, fastened the square crust lids in their places with thick paste made of plain flour and water. The paste showed in places, and fearing it might not be dry by morning, I slightly moistened the entire bottom of the roll, then dredged it with dry flour, and applied a hot flatiron, which dried the paste thoroughly, and browned the bottom of the rolls very handsomely. The loaf was treated the same as the rolls and filled with nuts.

For dessert we had a very large English plum pudding, in which a very great number of presents were contained—a finger ring, a velocipede, a boy's sled, skates, a knock-me-over-knick-knackery what-not stand, two monkeys that were painfully pushed head first over sticks, a child's cooking stove, a skipping rope, and a train of steam cars. It was easy to win Bridget over as an accomplice in this fearful undertaking, and together we did it.

The ring was covered very closely with tin-foil to prevent the dough working about the jewels. I then pushed a close fitting cork through the ring. This cork was for the purpose of buoying up the ring, otherwise it would sink to the bottom of the pudding. Over the cork and ring I rolled a thin coating of stiff dough coated with dry flour, which caused it to hold fast to the soft batter of the pudding just where it was desired that the ring should remain.

"Now for the velocipede, Bridget!"

Bridget shook her head and exclaimed: "Indade, Sur, but you can never do it!"

"Bridget," I exclaimed with terrible resolution, "Where there's a will there's a way. I'll just go round to the 'nice old

lady's' toy store, purchase the presents, then into the pudding they've got to go."

Returning in a short time, I demanded of Bridget full charge of the pudding until I got all the presents into it. I then sent her on an errand some six blocks away, so that she might not witness this wonderful performance. When she returned the pudding was in the pot boiling away like mad.

"Now, Bridget," I said, "not a word till the pudding is on the table, and then out will come the presents."

When dinner was over, Bridget brought on the pudding, holding it at arm's length, as though it held some evil spirit concealed within. The children looked slightly disappointed, and had evidently given up all hopes of any presents turning up at this meal. By this I inferred that they had not the least suspicion of what the pudding contained. Ned, being the eldest, was helped first. Scarcely had he attacked it, however, when he suddenly dropped his spoon and shot into the kitchen; in an instant I saw him dash past the windows and down the street. I next served Mary, who also quickly left the table, and seemed to take the same course as Ned. Presently back they both came; Ned with a velocipede and a pair of skates, his sister bowed down under a knock-me-down-knick-knackery stand.

All the children got their presents out of the Christmas pudding, and this is the way it was done: Cutting up a sheet of writing paper into four pieces, on each piece I wrote an order reading thus: "Mrs. Gray, please deliver to bearer articles marked No. 1." Each of the children was represented in the pudding by one of these orders. Before I placed the orders in the pudding, I folded each one into a small compass, and securely covered it with tin-foil, after which it was fastened to a piece of flat cork to keep it in its position on the top of the pudding. The corks were of different sizes, the largest one for the oldest child, and so on to the smallest cork, which represented the youngest. In this way I was sure of giving the right order to the right child. As I dealt out each piece of pudding, it was turned upside down, bringing the order underneath; over it all I poured the sauce, which gave the plate of pudding a very innocent look. The guessing as to what kind of a present the numbers on the orders represented, the journeys after the presents and having to help each other home with them, and the lots of thanks I got, will cause this wonderful Christmas table never to be forgotten.

In using these different disguises for the presents, I tried to retain the relative weight of each article used, so as not to excite suspicion by unusual lightness. Each article was firmly packed with cut paper to stop all loose feeling or looseness. Every article was plainly labeled with the name of the person for whom it was intended.

A. W. Roberts.

Lessons in Magic—II.

Skill in the art of palming, as explained in our last number, can only be acquired by persistent practice. The learner should therefore practice until he is master of every movement. In my next I shall explain, among others, the always popular "Obedient Cards," in which the cards rise at command from the pack, and in the meantime give one more trick depending upon the instructions given in the first lesson.

Passing a Marked Coin into a Lemon.—The performer borrows from one of the audience a coin, which he allows to be marked in such a way that it may be readily identified; and then gives it to a person to hold. He next produces two lemons, and allows the audience to choose one with which he shall do the trick. The chosen one he impales on the point of a knife, and approaching the person who holds the coin, requests him to take the knife by the handle, and hold it up high, so that the lemon may be in sight by the whole company. Taking the coin, which the gentleman has till that moment held, he closes his hand upon it, bids it "pass," and opening his hand, shows

that it is empty. He requests the person who holds the lemon to cut it open, and examine the coin which he will find inside, and say whether it is the one that was marked, which it invariably proves to be.

This trick is always attributed to "confederacy," the audience supposing that the person who cuts open the lemon and takes out the coin, is in collusion with the performer. Such, however, is not the case, as it is purely sleight-of-hand.

In order to perform it, two lemons are prepared by cutting slits in them large enough to admit the point of an ordinary table-knife. The next thing to be done is to determine what coin is to be used. I will suppose it to be a nickel five-cent piece. The performer takes one of these coins, and holds it concealed in his left hand, either by palming or otherwise. He is now ready to begin his trick, which he does by requesting one of the audience to lend him a five-cent piece. "Not a silver one," he explains, "but the ordinary nickel piece." Having got one, he asks several persons to mark it, that there may be no mistake about it when the trick is over, and then gives it to some one to hold. He tells him to hold it up, so that every one may be able to see it; "Not that way, my dear Sir; hold it so." As he says this, he takes it from him, under pretence of showing how it should be held, and instead of returning it, gives him the one he has held concealed in his hand. No one suspects for a moment that he has given him any other than the marked coin. He now produces the lemons, which he holds in such a way that the slit will not be seen, and when one has been chosen, he throws the other aside, and whilst going to his table under pretence of getting a knife, he slips the coin into the slit. He runs the point of the knife into the slit, and then hands both knife and lemon to the person who has the coin, and tells him to hold it up. Next he asks for the coin. He takes it with his right hand, lets it slip up his sleeve, and pretends to put it into the left hand. He manœuvres with the right hand, so that all may see it is empty, and then bids the coin to "pass" into the lemon. He opens the left hand shows that it contains nothing, and then bids the person who holds the lemon to cut it in two, and in the centre he will find the coin. Whilst the audience are watching this, the performer drops his right arm, and lets the coin which is in the sleeve fall into his hand, from which as soon as possible, he transfers it to his pocket.

The trick is now done, but, as the province of a conjurer is to amuse as well as astonish, he indulges in the following innocent joke:

The coin having been identified, he proposes to do something still more wonderful, no less a feat than that of passing half the lemon into the coin.

"No doubt, ladies and gentlemen," he says, "you think this an impossibility; but you must remember that I do not really do all that I seem to. I merely deceive your senses, and make you think I perform miracles."

"Now, Sir, hold the coin well up." He pretends to take half the lemon in his hands, but lets it drop into a pocket fastened at the back of his table, and with his hands together, as if holding the lemon, he approaches the audience.

"Now, sir, when I count 'three,' hold on tight to the coin, else the shock of the lemon passing into it may carry it out of your hand. Now, then, 'One,' 'Two,' 'Three!' 'Pass!'"

He opens his hands, to show that they are empty, and then bids the gentleman who holds the coin to *cut it open, and he will find the half-lemon inside of it.*

There is one very important part of this trick that I find I have neglected to explain, and as it is needed in many other tricks, I will tell my readers how.

To Change a Coin received from the Audience to a Prepared Coin.—Have the prepared coin concealed by being palmed in the left hand. Take the one loaned by the audience in the right hand, and, palming it, pretend to pass it to the left; show the

coin which is in the left hand, and it will be taken for the one that was borrowed.

This is a most useful feint, and by it the coin in the "lemon trick" is changed, when it is taken from the person who has it, under pretence of showing how it should be held.

Memory.

THE power of the human mind to remember any series of statements or facts, is greatly increased if we are enabled to see a distinct connection between them. The great difficulty of remembering a disconnected series of sentences was once well illustrated by Foote. Macklin was lecturing upon literature and the stage, and in discussing the education of memory, boasted that he could repeat any formula of words after once hearing it. Foote was in the audience, and at once wrote and sent to the stand that rigmarole that has since grown so famous: "So she went into the garden to cut a cabbage leaf to make an apple-pie; at the same time a great she-bear, coming up the street, pops its head into the shop. 'What! no soap!' So he died, and she very imprudently married the barber; there were present the Pincininies, the Jobolilies, and the Gayrulies, and the grand Panjandrum himself, with the little round button at the top; and they all fell to playing the game of catch-as-catch-can till the gunpowder ran out of their boots."

Macklin failed, and, short as it is, it is not very often that a person is found who can repeat it after hearing it only once or twice.

Pond and Stream.

OF all objects for microscopic study, there is nothing in my estimation to compare with the living objects of pond and stream. They will furnish more beautiful and interesting objects than the most complete cabinet. To this department the microscope should be more particularly devoted.

There is no question that from this kind of inquiry more important results may be obtained than from any other. Here it is not necessary to diverge from the main object (observation) to dissect, cut, slice, grind or polish, before you can examine, all of which requires abundance of leisure time, and cannot be very interesting as it is only a means of getting an object for examination, unless making a special study of an object.

Pond and stream life furnishes work for both high and low angled lenses, penetration or no penetration. It is a magnificent sight to get a rhizopod (*Difflugia proteiformis*), or a diatom (*Gomphonema elongatum*) drift across your field under a 180° lens; they sparkle like a Koh-i-noor, and then under a comfortable working lens, like the inch of 25° or 30°, take a survey of your pasture.

How interesting, under a low power, to get a diminutive view of some rare object or peculiar action, and then bring the matter up clear and enlarged with a higher power. How vastly easy is microscopical analysis in comparison with chemical! With the microscope the imperceptible is made perceptible at once; the chemical requires great labor and time. H. WATSON

Providence, R. I.

A Hint for Skaters.

Mr. Jos. G. Kitchell, of Cincinnati, O., sends the following, which may prove beneficial to those who, for the sport of skating, often undergo great personal risk: "Cut or select from the carpenter's lumber, a strip or rod of ash, walnut, maple, or any light yet strong wood, procure a round piece three-fourths of an inch in diameter, and about six and a half feet long. Take this with you when going to skate; grasp it near the centre with the right hand, and carry vertically; if the ice should break, and you sink, a little presence of mind and the rod, which you throw horizontally as the first cracking is heard, will prove very valuable, as you can keep head and shoulders above water until help arrives, or enable you to emerge entirely by shifting the rod, so that it rests on the thickish ice around the hole. You will find from a little use that it is not in the least an incumbrance, but it gives a graceful appearance to the skater, will often avoid a fall, and will insure a greater aid to beginners on skates, I think, than the helping hand of an interested expert."

Home-made Hanging Baskets—II.

(*Illustrated by A. W. Roberts.*)

THE variety of designs which may be worked out of even the commonest forms of ordinary earthen flower pots, and the great extent of common and otherwise worthless materials from which supplies may be drawn, encourages me to add a few more designs to those already given. It is a well known truth that it is labor guided by taste and skill that confers value upon most articles. Even the rude iron ore, which is trampled under foot and regarded as dirt, becomes, when worked into some products, worth more than its weight of the finest gold.

Fig. 1 is a nine-inch flower pot, bored full of holes of the size shown in diagram, Fig. 2. After the holes were bored, I gave the pot a coat of dark green paint, which was then dusted over with fine brown sand (washed clean and dried) mixed with white frosting or pounded white glass, to give the pot a glisten like granite and subdue the too painty look it might otherwise have. In the bottom of the pot, over the drain hole, was placed a large piece of sponge. This sponge was for the purpose of retaining a liberal supply of water for the very large number of plants used in this hanging pot, and was necessary from the fact that they are of a kind that delight in moisture. Over and around the sponge the pot was

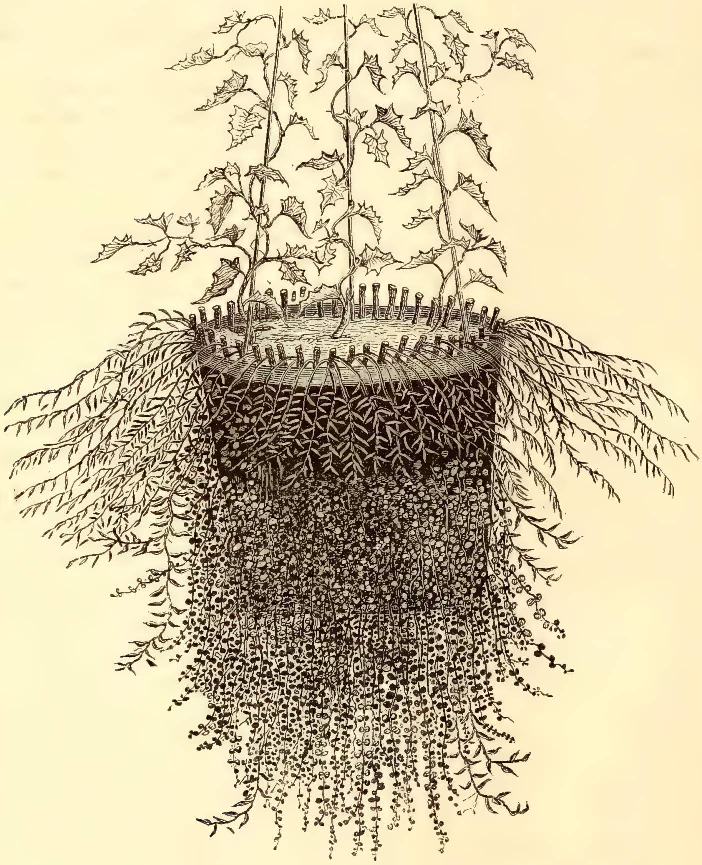

Fig. 1.

filled in with a layer of rich soil, reaching the first circle of holes. In these were inserted slips of zebra grass (*Tradescantia zebrina* and *T. aquatica*) also moneywort (*Lysemachia numularia*), covering them with earth well pressed about the slips. In this way the pot was filled to the rim.

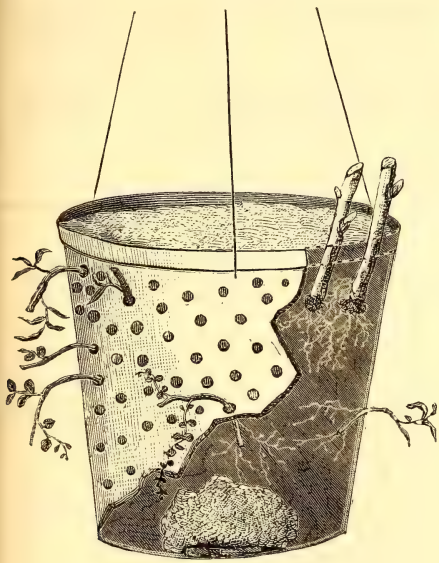

Fig. 2.

I next planted slips of willow (pointed at the ends, so as to enter the soil readily) around the inside of the rim of the pot, each slip having four buds, two for rooting and two for starting young sprays. If both buds started, the one facing the inside of the pot was pinched off. These slips of willow, in course of time, produced a long drooping spray over the top of the pot, giving a graceful effect. Inside the pot I planted German ivy, which was trained up the wires of the pot. Some of the slips of moneywort grew down from the pot a yard in length; these I looped up and tied to the willows.

Fig. 3 is an old fruit can, which was soaked in water to remove the label and paste, after which it was dried thoroughly and two coats of asphalt varnish applied. Around the can I worked designs with stove cinders or clinkers from a boiler furnace, selecting those of picturesque form, bright color and light weight. These were first washed and dried in an oven, and then fastened on the can with hard asphalt cement. I touched up the cinders with

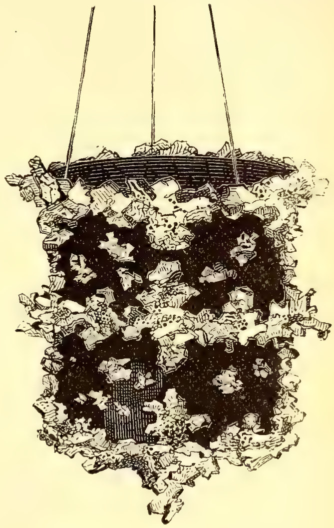

Fig. 3.

very brilliant colors in distemper. By distemper is meant dry colors ground in the smallest quantity of gum arabic as a fixative. I also used gold and silver bronzes for touching up the high reliefs. In some places the field of black varnish being large, produced a sombre effect; this was broken up with splashings of small pieces of cinders highly colored. Over all I applied a thin coat of furniture varnish. Through the bottom of the tin, from the inside, a hole was punched for drainage.

For richness of artificial effect in colors, texture, form and lightness of material, this combination of cast aside rubbish far exceeds any attempt I have made to utilize such articles.

Omitted.—The title page and index have made such inroads on our space this month, that we have been obliged to omit many things that otherwise would have appeared. Exchanges and correspondence have been held over, but will appear in the January number, which will be sent to all now on our books.

The Heavens for December.

BY BERLIN H. WRIGHT.

MERCURY will be brightest, as an evening star, Dec. 5-8, setting Dec. 6 at 5h. 44m., eve.—1h. 12m. after the sun, and 27m. before the end of twilight, at a point about 3° south of the Sun's path;* at star LAMDÆ SAGITTARII. On account of his extreme southern declination, this will not be a favorable opportunity to see Mercury, and doubtless many who are not accustomed to search the Heavens will fail to find him.

VENUS, being in superior conjunction with the Sun, Dec. 5, cannot be seen this month.

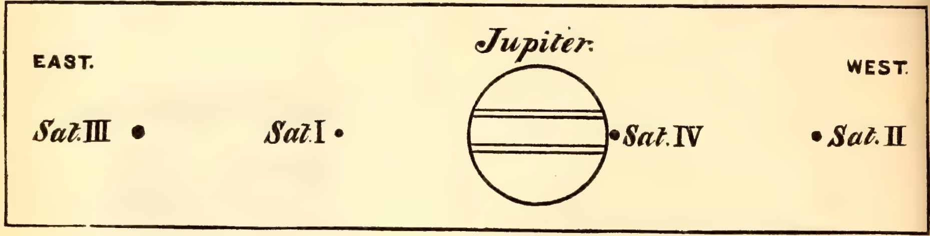

Fig. 1.

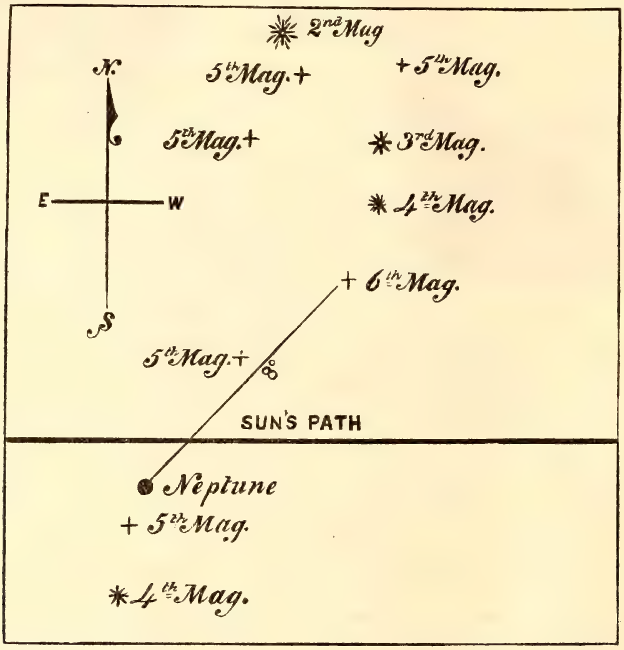

Fig. 2.

which time he will be very near the 4th magnitude

*For the convenience of the reader we give in this place several units of measurement. The "Ell and Yard," called also the Three Stars, Three Kings, and, in Job, the "Bands of Orion," rise about 7 o'clock in the evening. It is composed of three 2d magnitude stars in a straight line, just 3 degrees long, the middle star being 1½ degree from each extreme. This makes a good yard stick. The "Pointers" are the two stars which form the side of the Great Dipper, opposite the handle, and are 5 degrees apart. The two in the top are 10 degrees apart. The North Star is 28¾ degrees exactly north of the Northern star of the Pointers.

MARS will be within the quadrilateral of Libræ (composed of two stars of the 2d, and two of the 3d magnitude) until the 10th, and will enter the constellation Scorpio Dec. 22, following very closely the Sun's path. He rises as follows:

Dec. 5—5h. 1m., morning.
Dec. 15—4h. 57m., "
Dec. 25—4h. 53m., "

He will be 5° north of the Moon Dec. 21.

JUPITER will be a conspicuous object in the western sky throughout the month, setting as follows:

Dec. 5—8h. 20m., evening.
Dec. 15—7h. 51m., "
Dec. 25—7h. 22m., "

He will be about 1° south of the Moon Dec. 26, being in the constellation Capricornis, the Goat.

The following are the visible eclipses, etc., of his Satellites for December:

Satellite I.

Occultation, dis, Dec. 2—7h. 6m. evening.
Transit, end, Dec. 3—6h. 27m., evening.
Transit, end, (shad.), Dec. 3—7h. 30m., evening.
Transit begins, Dec. 10—6h. 8m., evening.
Transit begins, (shad.), Dec. 10—7h. 6m., even.
Eclipse ends, Dec. 11—6h. 41m., evening.

Satellite II.

Transit ends, Dec. 9—7h. 8m., evening.
Transit begins, Dec. 16—6h. 58m., evening.
Eclipse ends, Dec. 18—6h. 8m., evening.

Satellite IV.

Occultation, disappears, Dec. 27—6h. 13m., even.

At the time of the occultation of Satellite IV, the Satellites will occupy the positions shown in Fig. 1. The dot representing the Satellite is placed on that side of the number of the Satellite towards which the Satellite is apparently moving.

SATURN is the most favorably situated of the planets, passing the meridian as follows:

Dec. 5—6h. 51m., evening.
Dec. 15—6h. 13m., "
Dec. 25—5h. 35m., "

He passes the meridian at 6 o'clock in the evening, Dec. 18, being then 90° east of the Sun. He will be about 7° south of the Moon Dec. 3 and 30. His largest Satellite, Titan, may, with a very small telescope, be seen east of Saturn until Dec. 2, and after Dec. 18, being farthest from the planet Dec. 26. He will be west of the planet Dec. 2–18, being farthest west Dec. 10.

URANUS presents no features of interest to the telescopist, as he merely presents a faint bluish disc, when the most powerful telescopes are brought into requisition. When brightest (which will be in February, 1879) he may be seen with the naked eye, provided his situation is known. With an opera g ass he may be seen about 6° east and 2° south of the brilliant star Regulus, in the handle of the Sickle in Leo. (We say "Leo," but the head of the Lion, which is represented by the Sickle, is in the constellation Cancer, the Crab). Uranus rises as follows:

Dec. 10—10h. 28m., evening.
Dec. 25—9h. 28m., "

NEPTUNE, when brightest, may be seen with a telescope of 2-inch aperture, using as high a power as such an instrument will bear. He is moving westward among the stars in the western part of the constellation Aries, the Ram, passing the meridian as follows:

Dec. 5—9h. 24m., evening.
Dec. 15—8h. 44m., "
Dec. 25—8h. 4m., "

Fig. 2 shows the position of Neptune with respect to the surrounding stars. He may be known from the neighboring star by having a paler and steadier light. His position will not vary perceptibly from this for several weeks, as his apparent motion is very slight.

METEORS OR SHOOTING STARS.—There seems to be one one well-marked shooting star epoch in December—Dec. 6-13. We believe its period of maximum display is not known. The constellation Gemini is their radiant point. The centre of Gemini rises Dec. 15, 6 P. M., and passes the meridian at 1 A. M. Hence if any meteors are seen in early evening they will shoot upwards from the eastern horizon.

THE

YOUNG SCIENTIST.

PUBLISHED MONTHLY.

Past and Future.

TO-DAY we stand on a dividing line which marks a notable division between the past and the future; between accomplished fact and prospective hopes. The number now issued completes the first volume of the YOUNG SCIENTIST, and fills our contract with by far the greater number of our subscribers. On looking over the pages of the twelve numbers which we have issued, we feel that it would be difficult to procure elsewhere for the small sum of fifty cents, an equal amount of matter of the same quality. We have spared no expense for either articles or illustrations; the question with us has never been, "What will the article cost?" but "How good is it?" and although the journal is still very far from our ideal of what it ought to be, yet we feel that we have no reason for discouragement.

Next year, however, we hope to effect notable improvements in every department. We have in our pigeon holes several articles of great value and interest, and we have the promise of more. These articles will be illustrated by the work of the best draughtsmen and engravers in the country, and, as we have already announced, each number will consist of sixteen pages instead of twelve as heretofore. We feel confident, therefore, that those who join us on the voyage of 1879, will have no reason to regret it.

That the YOUNG SCIENTIST was needed, is abundantly proved by the deep interest which has been manifested in its success. Its circulation has already reached that of many much older journals, and the strong hold which it has taken upon the kindly regards of its readers, is shown by the fact that we have upon our books several subscriptions for two or three years. We fully appreciate this confidence and liberality,

and will do our best to render a proper return by making the journal as good as possible.

Our readers must, however, bear in mind that the more subscribers we get the greater will be our power to give them a good thing, and therefore we trust that every subscriber will not only renew his own subscription promptly, but endeavor to get some of his friends to join him. Our club rates are liberal, and our premiums valuable; we ask no one to work for us for nothing, and we look forward to an enormous subscription list during 1879.

But however this may be, we thank all our readers for the support they have given us during the past year, and we wish them all "A MERRY CHRISTMAS AND HAPPY NEW YEAR."

A Word to Parents.

IT is an unfortunate fact that the country is flooded with juvenile literature which, if not of a depraving kind, is, to say the least, debilitating to young minds. No boy whose mind is filled with dime novels, and whose feelings and imagination are excited by the false romance and adventure therein depicted, can possibly be in that healthy intellectual condition which gives promise of success either in work or study. And yet we find on every hand books and papers of this exciting kind. In the city of New York alone, it is said that there are twenty-five boy's papers of this class; and to crown this horror, a clergyman in a neighboring city announces a book devoted to "Night Sides of City Life," *illustrated*, and published at a price—fifty cents—which places it within the reach of every boy. Already one firm has ordered five thousand copies of this book in advance of publication, thus showing that a large circulation is expected amongst families and the young.

No teacher of youth, and no parent of thoughtful experience can fail to see that this book will do more harm during the next year than the author will be able to do good during the remainder of his life. And it is a matter of congratulation that such a volume is not to be published in New York, bad as this city is said to be, but has to issue from the press of a western and hitherto unknown publisher.

In view of these facts, the important question comes up—How shall we counteract the effect of this vile literature? To this question every religious teacher will, of course, have an obvious answer, but it seems to us that there is another influence which cannot be safely overlooked, and that is the influence of useful and instructive occupation. Give the boys something to DO in their leisure hours. Mere reading is not enough. They must have work in which they are interested, and in this connection it is well to remember that the education of the hands is quite as important as the education of the mind. Therefore, give them tools and teach them how to use them. Let them make work-boxes for themselves and sisters; kites and boats for themselves, and ornamental and useful articles for the household. Let them learn how to work out new designs for these things, and how to copy old ones. Once they become interested in these things and attain a certain measure of success, dime novels and accounts of night adventures in the city, even though these adventures be by a minister, will become stale and insipid.

To teach the boys (and girls too) the use of tools and simple instruments, such as cheap microscopes, telescopes, etc., is the aim of the YOUNG SCIENTIST. We believe that the antidote we have pointed out is one of the most efficient, and we propose to do our part to place it within the reach of all.

A Simple Method of Copying Drawings.

The following is a simple and easy way to obtain copies of drawings. If the drawing is in a book, or is one which it is desirable that it should not be defaced or injured, it will be necessary first to make a tracing of it, which is done in the following manner: Take a piece of tough vegetable tracing paper, such as may be obtained at ordinary book stores, and cut it so that it will be about an inch larger all around than the drawing. Lay it over the drawing, and with a moderately hard pencil trace over the lines which it is desired to copy.

Now take a piece of the same tough tracing paper, half an inch smaller than the tracing, and lay it on a smooth elastic surface, such as

is formed by several thicknesses of writing paper laid together. Mark over the surface of this tracing paper with a very soft lead pencil, so as to cover it completely with the pencil lines, with the exception of a small margin around the edges. With a small piece of wash leather or chamois skin, rub over the penciling so as to blend the lines, but not hard enough to rub off the lead. This prepared tracing paper is the transfer sheet.

Lay the tracing on the paper on which the copy is to be produced, and mark where the corners of the tracing come, so that it may be again placed in the same position. The transfer sheet must now be laid on the paper, inside of the marked corners, and with its penciled side down. The tracing can then be laid in its proper position, and fastened temporarily with pins or thumb tacks. With a sharp-pointed, very hard pencil, go over the lines of the tracing, using a moderate pressure, and being careful that no lines are missed. On removing the tracing and transfer sheet, a copy of the tracing will be found on the paper.

The copy thus obtained can be used as a ground work, and can be reinforced as much as the draughtsman may wish.

This method of transferring is better than that with the ordinary manifold paper, especially if it is desired to work over the copy with india ink, because the lines being the same as ordinary pencil lines, do not interfere with the flowing of the ink, and they can be easily erased, while the ordinary manifold paper being prepared with lard or oil, leaves an oily line which prevents the ink from adhering to the paper.

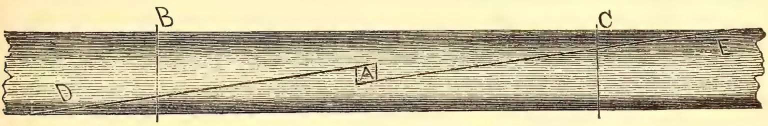
In many cases the drawing which it is desired to copy can be used instead of the tracing. The transfer sheet, being black on one side only, does not soil the back of the drawing.

The transfer sheet can be used a number of times, and if the lines grow dim it can be penciled over again.

The Shoulder and Collar Wedged Spliced Joint.

For permanent, or glued up and tied joints, this splice appears to be first-rate where the cane or wood is of sufficient thickness to allow such a joint to be made. The spliced rod is shown in the accompanying sketch; also the wedges fo- the hole, A. The ends of the

wedges are to be cut off when the splice is firmly wedged. If the splice is to be glued up as a permanent one, it must be closely tied with waxed silk or fine thread, and varnished. If used as a movable one by the riverside, a slightly tapered ferrule must embrace the rod from B to C, fully covering each end of the joint. This splice, also, might be used in the joints of a rod not permanently glued up and tied (all being secured by a sliding ferrule), if the fisherman chose to be at the trouble of punching out the wedges at the end of a day's fishing. Metal wedges might be advantageously used, if properly made of true exactness to fit the square hole in the centre of the splice.—*Exchange.*



THE SHOULDER AND COLLAR WEDGED SPLICED JOINT.

Fire-Proof Dresses.

At this season, when tableaux, private theatricals and similar entertainments, bring together light dresses and bright lights, it may be useful to know how to render even the most gauze-like dress perfectly uninflammable. By the use of the means now at the command of science, many a valuable life might be saved.

Some years ago Queen Victoria appointed a commission to investigate this subject. It was found that there were but four salts which were applicable to light fabrics: 1, Phosphate of ammonia; 2, a mixture of phosphate of ammonia and chloride of ammonia; 3, sulphate of ammonia; 4, tungstate of soda. Of these, the best was tungstate of soda, a salt which is not

by any means expensive. Sulphate of ammonia is objectionable, from the fact that it acts on the irons and moulds the fabric. The tungstate of soda is neither injurious to the texture or color, or in any degree difficult of application in the washing process. The iron passes over the material quite as smoothly as if no solution had been employed. The solution increases the stiffness of the fabric, and its protecting power against fire is perfect. This salt offers only one difficulty, viz.: the formation of a bitungstate, of little solubility, which crystallizes from the solution; but it was found that a very small percentage of phosphate of soda rendered the tungstate quite stable. The best method of applying these salts is to take one ounce of tungstate of soda and a quarter of an ounce of phosphate of soda, and dissolve them in a quart of water. The goods are moistened with this solution before being starched, and they may be afterwards ironed and finished without the least difficulty.

Articles prepared in this way are perfectly uninflammable. They may be charred by exposure to fire, but they do not burn readily unless there is some extraneous source of heat, and they can not be made to burst into flame. By the aid of this discovery, a lady dressed in the lightest muslin might walk over a row of footlights, and the only result would be that the lower part of her dress would be injured. Unless her person actually came in contact with the gas flames, she herself would suffer no injury. In country places, where tungstate of soda cannot be procured, a mixture of three parts borax, and two and a half parts sulphate of magnesia, in twenty parts of water, may be used with good effect.

Hints on Filing.

Cleaning the File.—The dust or small particles removed from the material operated upon, are always more or less liable to clog and fill the teeth; this tendency is especially aggravated when the file is used upon wood, horn, and such other materials, as, upon being mixed with the oil in the teeth, become baked when dry, and thus prevent the teeth from penetrating the work, to say nothing of the appearance of being worn, or the tendency to injury from rust.

It therefore becomes necessary that the file should be cleaned, not only at intervals during its use, but carefully before being laid aside, if the best results are to be attained.

This cleaning is done in several ways; sometimes, in the finer files, by rubbing the hand over them, or by drawing them across the apron of the workman; at others, by striking their edge upon the bench or vise, and again (which is a more common method upon the larger files), by the use of a strip of old or worn out card clothing, tacked to a piece of wood, having a handle shape at one end—a device which is usually rudely constructed by the operator.

In removing oil from the teeth of a new file, a ready way is to rub chalk or charcoal across the teeth and brush thoroughly. By repeating the operation a few times, the oil will be entirely absorbed, and the file will be in its best possible condition for use upon cast iron.

When the teeth of files are clogged with wood, or other soft substance which has become baked into them, if held in boiling hot water for a few moments, the imbedded substance becomes so loosened, that it may easily be carded out of the teeth. If the operation be quickly performed, any moisture remaining will be readily evaporated by the heat retained in the file.

Care in Putting Away.—One of the most destructive customs among a large number of mechanics of the present day is that of loosely throwing their files, fine and coarse, small and large, into a drawer filled with cold chisels, hammers, turning tools, etc., and then throwing the chisels, hammers and other tools on to the files.

Now when we consider the small portion of the points of the teeth which is worn off by use in an extreme wear, and that to effectually dull them for some kinds of work requires but the slightest rubbing upon a hard substance, it will be easily seen that the evils of this habit should be more carefully considered, and suitable provision made to avoid its destructive tendencies.

Starch Paste.—Two ounces of starch, one ounce of white glue, half an ounce of acetic acid, a few drops of oil of cloves. Dissolve the glue in cold water and then boil. Mix the starch with cold water, and pour into the glue while boiling.

To Polish Steel and Iron.—It is a fact well known to chemists that potash and soda, particularly the carbonate of the latter, prevent rust in iron. Mechanics are also well aware that cutting tools moistened with soap, leave a much cleaner surface on iron than when dry or used merely with oil or water. These facts have led to the use of a mixture of emery and soap, with excess of carbonate of soda, for polishing steel and iron, and the results have been very satisfactory.

The Population of the World.—The latest edition of Behm and Wagner's "Bevolkerung der Erde" gives the present population of the earth at 1,439,000,000, as compared with 1,424,000,000, as given in the previous issue. These figures are based upon the most recent censuses taken in various countries. The population is divided as follows: Europe, 312,398,480; Asia, 831,000,000; Africa, 205,219,500; Australia and Polynesia, 4,411,300; America, 86,116,000.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, JANUARY, 1879. NO. 1.

Growing Plants in Sleeping Rooms.

MANY persons who have no opportunity to cultivate a garden, are so fond of living plants that they cannot get along without them; they therefore grow them in pots in the rooms in which they live and sleep, and we confess that during the dull days of winter, when everything outside is reduced to dusty brown or clothed in white, a little bit of green is wonderfully pleasant and refreshing. This window gardening or house-plant culture, is generally confided to the girls (and by the way, we like that hearty old word which indicates so much that is pleasant and lovable, as contrasted with the modern expression "young lady."). Their refined taste and patient attention enable them to succeed and make things pleasant where boys too often fail. It frequently happens, however, that some big brother, fresh from the chemical or botanical classes of school or college, wants to have the plants all turned out of doors or pitched down cellar, and he so overwhelms his less scientific sisters with talk of carbonic acid, carbonic anhydride, oxygen, ozone, etc., etc., that however the tears may come, the plants have to go.

Now before putting the edict of banishment into effect let us see whether all this argument and these

"Words of learnéd length and thundering sound"

really furnish good sound reasons for depriving the girls of their pets.

It is well known that plants are the great agents in keeping the air pure and wholesome for animals. Whenever an animal breathes, it gives off carbonic acid, and this carbonic acid (called also carbonic anhydride and carbonic di-oxide,) quickly extinguishes life when it is present in too great proportions. Hence, when animals are confined in close boxes or apartments they speedily fall asleep and very soon die. Under the influence of sun-light, however, the plants absorb this carbonic acid; they decompose it into its component parts, oxygen and carbon, and while the latter is used for making starch, sugar, woody fibre and other parts of the plant, the oxygen is given out and serves to make our fires burn and to enable animals to breathe. It is only by the help of light, and strong light at that—such as the light of the sun or burning magnesium, that plants are en-

abled thus to decompose carbonic acid. During the night they give off a part of the carbonic acid which they absorbed during the day, and which for want of light, they are unable to decompose; and therefore it has been held that plants must be injurious when kept in sleeping rooms.

But while it is quite true that plants give off carbonic acid during the night, the extent to which they do this is so slight, that it may be safely overlooked, especially when we remember that there are so many other agents of far greater power, at work in the same direction. A common student lamp gives off more carbonic acid during the night than would a whole houseful of plants. Even a candle will give off more than would be exhaled by all the plants in the conservatory of the most ardent lover of flowers. A child, breathing for five minutes, will throw off more carbonic acid than a windowful of plants would do in a week, and yet who ever was afraid of staying in the room with a child? The injury which even a large collection of plants is capable of doing to the air is as nothing compared with that to which the presence of a strong, healthy man gives rise. Indeed if there were any foundation for fear on this score, a greenhouse or conservatory would, towards morning, become one of the most deadly places a person could enter; yet who ever felt inconvenience from a walk through a conservatory in the early morning? And how refreshing is the air of such an apartment when compared with that of a ball-room where the dancers have been in active exercise, and consequently have consumed the oxygen with more than ordinary rapidity!

We may therefore safely conclude that on this ground, there is no valid objection to the presence of plants in sleeping or living rooms.

There are, however, certain plants which give off powerful odors, and which should be carefully avoided. It is impossible to give a list of plants which are objectionable on this score, for it has been found that different constitutions are differently affected in this respect —plants which are entirely harmless to some being almost deadly to others. The rule ought therefore to be to exclude *all* plants which give off a strong odor, either through their leaves or flowers. If this rule be strictly adhered to, no danger will be incurred.

The Art of Bust-Modelling and Casting.

BY ADELAIDE F. SAMUELS.

THE first day you can do nothing but prepare the clay, which can be procured at any Italian image-caster's shop for two or three cents a pound, and fifty pounds will be sufficient to make a life-sized bust, with drapery.

Preparing it, or setting it up for the bust, is the only disagreeable feature in modelling; all artists agree to that.

The clay is set up in the following manner: Wet the top of your modelling-stand—if you have not one with a revolving top, an old shoe box on end will answer the purpose—then with a wooden mallet, *pound* upon it your clay, piece by piece, until you have a *solid mass, without flaws*, as high and as broad as you intend your bust to be. The clay must be neither too wet, nor too dry, but just moist enough to cling readily together.

Now, if you are quite sure your clay is well pounded, you can cover it with a wet cloth and leave it over night to *shrink*, while you take a

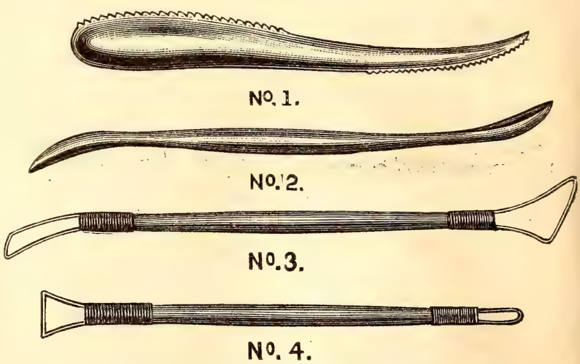


Fig. 1.—Tools used in Modelling in Clay.

look at some of the tools you will require, most of which can be made by any smart boy or girl, but if you prefer to buy them, they can be procured at the image-caster's, where you bought the clay.

Tool No. 1 is mostly used to get a *level surface* on the clay, by drawing the teeth repeatedly over it in *opposite directions*. It can be easily made out of hard wood.

No. 2 is also made out of hard wood, and is used to get a *polished surface* by pressing the spoon-like end upon the clay, and working the tool about in little circles; it is also used to "dig" with.

Nos. 3 and 4 are wires, bent, as shown in the figures, and *bound firmly* upon wooden handles; they are used to pick and dig with.

You will want, at least, two sizes of each kind, and besides them, a pair of dividers and a pair of calipers. The dividers or compasses are well known; the calipers must be large, and capable of being fixed at any distance apart by means of a set screw. The best form of this tool is drawn in Fig. 2. They should be at least a foot long. Those will be all the tools you will need for the clay, though you will see a greater variety at the image-makers.

Many persons suppose that the "Image-makers," as they are called, *design* the images they cast in plaster. That is a great mistake: very few, if any of them, do so. They are designed in clay first by artists; the clay model is then covered by a plaster piece-mould by the plaster worker, who can turn out a great number of "copies" in plaster from one mould before it is worn out. The artist usually gets a percentage on every copy sold, and sometimes, when an image is "something striking," it proves very remunerative both to the artist and the caster.

Nearly all the artists understand the art of

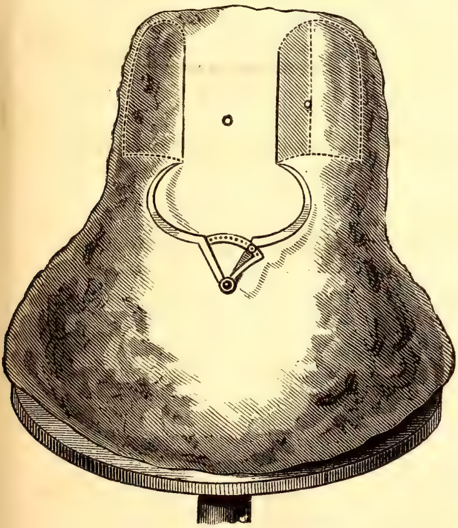

Fig. 2.

casting, but all seem to dislike working in plaster. You will be able to judge whether you will like it or not before you have finished this series.

The next day you can begin to take measures for the *profile*, which is always the first thing to be done in bust-modelling.

Unless you have a very true eye for outlines you will have to go by measurements almost entirely, and in order to have a point on your clay that you can measure from in every direction, you must first find the distance between the two ears of the sitter with your calipers, by placing the points on the fleshy knobs at the entrance of both ears; be very sure that the points *just touch* the flesh on both sides, but do not press it in, then screw up the calipers and you have your first measurement, which you will make use of in the following manner.

Suppose Fig. 2 represents the mass of clay as you built it up; it is, at least at the top, twelve inches thick; while, by placing the points of the calipers on a rule you find the sitter measures from ear to ear only, say, five and one-half inches.

Take the calipers, screwed up as they are, and mark with them two lines down the middle of the clay as represented in the cut, about as long as the face is to be, then make the dot between them, which will be where the end of the nose is to come.

Now, with the calipers measure the sitter from the end of the nose to the knob at the entrance of one ear. Take a large knife and cut away the clay carefully from both of the

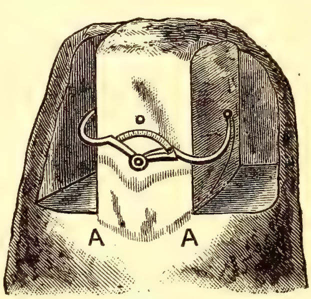

Fig. 3.

straight lines, as shown by the dotted lines in Fig. 1, until you can get both measurements on the clay—from ear to ear, and from the end of the nose to each ear.

If the face of the sitter is very full, so that the distance across any part of it measures more than the distance from ear to ear, you must allow for the fullness, as shown in Fig. 3, by rounding out the clay beyond the straight lines, instead of cutting it down even with them.

In order to get the screwed up calipers back

to take the ear measurements, without injuring the fullness on either side, place the points of them at A A, Fig. 3, where it need not be full, and run them back, then up, in the direction the dotted line takes.

Now, if you look at the sitter, you will see that the knobs at the entrance of the ears are not on a line with the end of the nose: they will doubtless be a trifle higher; stick a pin in the clay on both sides, just where the knobs should be, and you have your points to measure from in every direction, as shown in Fig. 4.

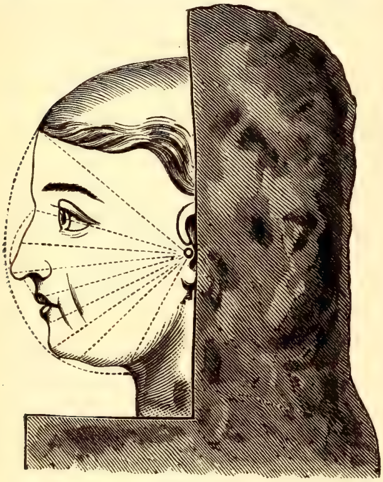

Fig. 4.

You have already the distance from the end of the nose to the ear; you next want to find the height from the end of the nose to the hair on the forehead with the dividers; mark the clay to keep the measurement, then with the calipers find the distance from the same point on the forehead to the ear, and work away the superfluous clay with tool No. 1, until you can make both measurements to a nicety.

Next measure the length of the nose with the dividers, then the distance from the top of the nose to the ear, with the calipers. While working away the clay for these measurements, you must look at the sitter's profile occasionally, to get the correct outline.

Now find the length of the upper lip, then its distance from the ear, and after working out those measurements, find the distance from the nose to the chin, then from the chin to the ear; and so on, as shown by the dotted lines; being very sure that you measure correctly, as the eighth of an inch, only, makes a difference in a likeness.

Put all the pieces of clay you cut off in a box by themselves, and water them occasionally; they will have to be used by and by. The same clay can be worked over and over for years, if kept free from dirt.

The clay you are modelling will need wetting by this time. If you have a syringe such as gardeners use to sprinkle plants with, you will have just the right thing to go over it with; if not, pour water slowly over it; it must be kept moist all the time or you can do nothing with it. At night, or when not working upon it, always keep it covered with a wet cloth, or, what is better, cover with oiled silk a frame that will just slide over the clay without touching it. That will keep the air from it, and does not disturb the clay as the wet cloth is apt to.

The modelling-stand must be in a *good light;* directly opposite a high north window is the very best.

To be continued.

Wood-Carving. III.

DIAPER-CARVING.

THE simplest of all kinds of carving is that known as "diaper-carving." The tools are simple and cheap, and the work easily learned.

One of the most suitable objects for this kind of carving is a book cover. In olden times books were generally bound with wooden covers, and hence the use of the word "board" as applied to the cover of a book. The books most suitable for this kind of binding are albums, scrap-books and books for dried plants or seaweeds. The carved covers give them an antique appearance, and hence the kind of wood that is chosen should have a flavor of antiquity about it. Black walnut and oak are good; avoid mahogany, rosewood and that class. Having procured a piece about a quarter of an inch thick that has a nice grain, solid and firm texture, and is dry and well-seasoned, cut out the pieces intended for the sides to exactly the size that is wanted Bevel off the edges and have the entire surface, except that intended for the inside, finely French polished. This you may be able to do yourself, but if not, any cabinetmaker will do it for you for a trifle. If you are easily pleased, you may rest content with a finely varnished surface, but the effect of French polish is so much superior in contrast with the rough diaper work, that you should secure it if possible.

The piece is now to be fastened to a good-

sized block of any common wood, so that it may be easily held during the process of carving. The carver generally has a few blocks of different sizes that he keeps for this purpose. They are planed smooth and true, but not oiled or varnished. To fasten the piece to one of these blocks or "working boards," as they are called, glue a piece of fine but stout white paper on each of the four corners of your blocks, and also a patch in the middle; then cover these patches with glue and press them on your working-board; and as soon as the glue is dry you are ready to commence operations.

Fix upon some simple pattern, which should have rather an antique cast. We give two of these as examples, Fig. 1 being complete, but greatly reduced in size, while Fig. 2 is nearly full size for a small book, but shows only one-half of the pattern. These patterns may be easily enlarged or reduced by means of the pantagraph—an instrument which every young

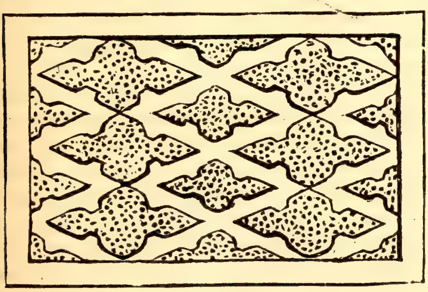

Fig. 1.

carver and scroll-sawyer should have. (In our next issue we will tell you how to make a much better one than you can buy.) Having selected your pattern and drawn it perfectly and neatly on good stout paper, trace it over on some tough tracing-paper; then pin it—or better, paste it—on the beveled edge of the block, so as to fix it firmly. Now take the tracing-point, and go over the whole pattern carefully, so as to leave a fine line everywhere. Remove the pattern, screw the board down on the table with your clamps, as described in former articles, and see that it is quite firm. Take the V, or parting-tool; hold it in your right hand at a

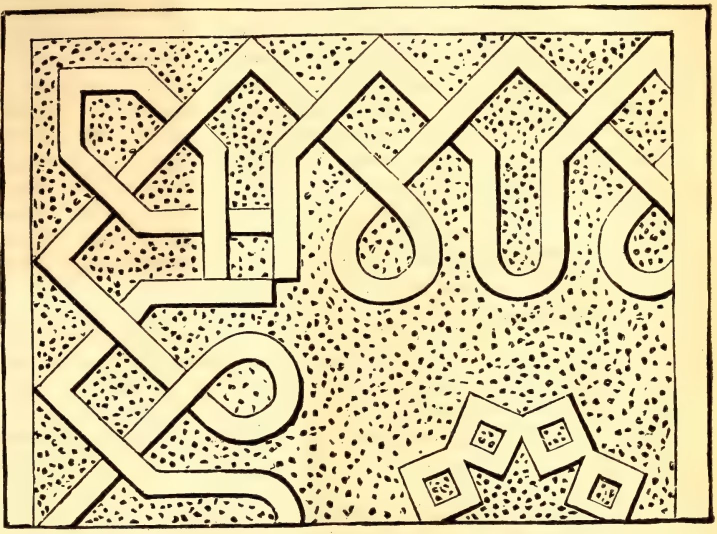

Fig. 2.

proper cutting-angle, put your left wrist on the wood to be operated on, pass your hand over the steel, the thumb underneath and the tips of the fingers resting on the work. This will give you perfect command of the tool, will prevent its slipping forward, enable you to guide it round the curves, and the thumb being under the tool, you can grasp it any moment with the whole hand. Take out no more wood than is just sufficient to mark the pattern well. Then take the star-punch, and hitting short, sharp strokes with the hammer, begin and punch down the wood as marked in the illustrations. While punching the wood, you must slightly turn the punch round after each stroke of the hammer, so as not to give the grounding a liney appearance; and one more caution—if you see that the punch raises little chips of wood, try the other way of the grain. When the work is finished, take a common table-knife, pass it between the piece of work and the board, and the paper will split in half easily, and the work will become detached. Scrape off the paper and glue, and the work is done.

The effect of this diaper-carving is very good, the punching down of the wood throws the pattern up in relief, requires but little care, and is easily done. You should practice a little with

the V tool on a spare bit of wood before trying it on your book-cover. The faults to be guarded against are cutting too deep, going off the line, not sweeping smoothly round the curves and punching to irregular depths, owing to variations in the force with which the punch is struck. You can, if you please, mark the straight lines with a chisel and the curves by a gouge, holding them quite upright, and pressing them down with the hand. Many persons do diaper-carving in this way without using the V tool. In our next paper we shall take up the subject of fret-cutting and perforated carving.

To be continued.

Engraving on Wood.

BY SARAH E. FULLER.

THE readers of the YOUNG SCIENTIST are no doubt familiar with the terms "Wood Cuts," or "Wood Engravings," and many probably know how they are made. But for the benefit of those who do not know, we will briefly describe them.

Examine any wood engraving, and it will be found to be made up of lines,—black lines and white spaces. These lines and spaces are sometimes so fine and small that they can hardly be seen without the use of a magnifier. Indeed the work is usually done with the aid of a glass, usually of low power. The white spaces are cut out of the wood, leaving the black lines in relief. No matter how fine the white line or dot, a fine tool has cut the minute chip out of the wood; and larger tools have cut out the larger white lines and spaces, different sizes being used according to the judgment and skill of the engraver.

All this will be more readily understood after a careful examination of the accompanying figures. In the first picture you will notice that the veins and network show white on a black ground. These have been cut out leaving all the black in relief. The second picture is the same subject; here, as before, the parts which show white have been cut out, but this time the veins and delicate lines of the network are in relief. And Figure 3 is an example where nothing has been engraved—a block the same size as the two preceding examples, but no work upon it.

Examine the illustrations of the YOUNG SCIENTIST and you will find them more interesting than before, for in order to make a good representation of any object, much thought and labor has been required.

Fig. 1.

As the name implies, a "wood cut" or "wood engraving," or "engraving on wood," is an engraving which is cut on wood. For fine engravings, boxwood imported from Turkey is used; this wood grows in the interior of the

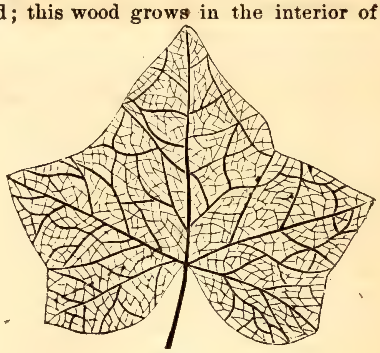

Fig. 2.

country, and is brought to the seaports on the backs of mules, in logs, the diameter of which seldom exceeds eight or ten inches. In our principal cities, there are dealers who make a business of preparing these logs for the use of engravers, and any boy or girl who wants to engrave, can have these prepared blocks sent by mail or express.

Boxwood is chosen for fine engravings because it has a close, even grain, permitting lines to be cut, without breaking or chipping out. When it is not essential that these lines shall be very fine, apple, pear, maple, cherry and mahogany woods are used. For large bill-posters pine boards are used, and tools especially adapted for cutting with the grain of the wood; but this form of wood engraving does not properly belong to our subject.

But for wood engravings such as you see in the YOUNG SCIENTIST and illustrated books, the pictures are made on boxwood, and on the end of the grain. The wood is sawed across the grain into slices, so that when smoothed and prepared for use, the slices are as thick as type is high, which is fifteen-sixteenths of an inch.

Fig. 3.

We will now suppose some boy or girl has a well-seasoned piece of any of the above named woods, sawed, and evenly planed and scraped to the right thickness. It is not necessary to plane both sides of the slices,—the sawing should be true, however. The next step will be to take a piece of pumice stone, with one side ground off flat. Grind the pumice stone on a brick or slab of stone, by rubbing it a short time. Wet the planed side of the wood, a little, and with the pumice stone smooth and polish the surface, being careful that specks of grit or the edges of the pumice stone, do not make scratches. Do not use too much water, or the block will swell and warp, and perhaps crack. Use just enough water to let the pumice stone pass easily over the surface. Use the pumice stone lightly, that is, do not bear down heavily on the surface, and when there is fine ground wood mixed with the water, rinse it off. If the surface needs farther rubbing, go over it with the pumice stone again, but do not work with a paste of ground wood and water accumulated on the surface—keep the block free. If the block has been well planed and scraped, the "pumicing" ought to be quickly done. The object is to remove any slight inequalities or shiny places left by the plane. While the block is yet damp, take some fine white lead, quite free from grit, and dust a little on the block, or use prepared water color white, or an enameled card may be rubbed over the damp surface and the enamel will come off. Then with your fingers distribute the white carefully over the whole surface, so as to make a very thin even coat of white—so thin that it will show the wood through it, while it is wet, and when it is dry it will be white enough. Set the block on its edge to dry—not near a fire, or in the sunshine—let it dry slowly. The blocks should always be placed on their edges, there being less danger of warping than if laid on their surfaces. We whiten the blocks because the pencil "takes hold" better than on the bare wood, and also because the drawing shows more clearly.

When the block is dry, the next step is to draw the picture or design on the wood. We have the design before us on paper, it may be a sketch only in outlines, or it may be a shaded picture. Cover the drawing with a piece of tracing paper, the best kind of which is very transparent. Fasten it so that it will not slip, the most convenient way is with yellow beeswax, several small scales being used. It is best to have the picture lying on a drawing-board, and fastened so there will be no danger of slipping while tracing the outlines. The points used by draughtsmen are very convenient, or mucilage or beeswax can be brought into service. Trace all the outlines of the picture on the tracing paper with a moderately soft pencil—the grade HB is very good. Have the point of the pencil long and sharp. After cutting it with a knife to the shape needed, the point can be finished by rubbing it on a piece of fine sand-paper, or a fine file. It may be repointed in the same manner, as often as is necessary during the process of tracing. After tracing the outline very carefully, loosen the tracing paper and lay it face downwards, on the prepared block. Fasten the edges to the side of the block, either with mucilage or beeswax, whichever is most convenient. With a metal or ivory point (an old-fashioned stiletto is good), or a hard pencil, retrace the pencil outline, which will show very distinctly against the whitened surface of the block.

DR. ABEL, the Berlin correspondent, has been lately staying with Lord Beaconsfield at Hughenden Manor. Dr. Abel is known to read and translate upward of seventy different languages, and though a German by birth, yet his English writing is clear in meaning, simple in diction, and polished in style.

Lessons in Magic.—III.

THIRTY years ago or more I attended the opening performance of Herr Alexander, a Magician, at the Minerva Rooms, which old New Yorkers will remember as a very pleasant hall, and there saw, for the first time in *my* life the "Obedient Card," which I promised in my last, to explain. It was an old trick then and, consequently, is not a very new one now, but it is good, and always "takes."

The performer asks five or six persons in the audience to select cards, and when they have been chosen and replaced in the pack he returns to the stage and lays the cards on his table. He then hands out for examination a small metal box, of such a size that a pack of cards will just fit in it. This box, the technical name of which is *card-rack,* is open at one end and partly open in the front, and has a piece of tubing soldered at the closed end. It is very much the pattern of a *faro box,* but as my readers may never have seen that dangerous plaything, and I trust never will, they can form an idea of what is needed by this illustration.

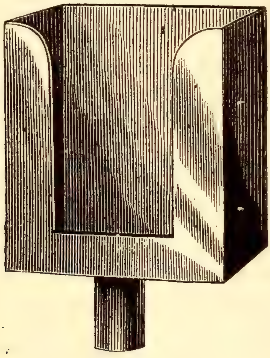

Fig. 1.

When the audience have been satisfied that there is no preparation about the box, it is stuck on the end of a pole, which is fastened to the stage, and the pack of cards is placed in it. Then as they are called out each card rises in turn from the pack.

The preparation for this is very simple: A piece of black sewing silk is fastened to the top of one of the first cards in the pack and then led over the top of the pack. The last of the cards selected by the audience is then forced down into the pack carrying the silk-thread with it. Then another card, and another, until all have been pushed into the pack, each carrying the thread with it. Between each of the chosen cards there are three or four others, and over the tops of these the thread always passes while it goes under the chosen ones. The loose end of the silk-thread is led off to a confederate who is concealed, and, it stands to reason, that when he pulls the thread the last card that was pushed down will come up and when he pulls again, the next will come, and so on till all have appeared. This prepared pack is laid on the table with several others, and after the *card-rack* has been examined and placed in position, this pack is taken up, instead of the one from which the cards were drawn, and placed in the *card-rack.*

The effect of the trick may be heightened in very many ways, as for instance: Among the cards that are drawn let one be a queen. When it is time for it to arise from the pack, the performer approaches the person who drew it, and requests him to tell it to "come up." This he does, but strange to say, no card appears. "What was your card, sir?" you ask.

"The queen of hearts," he replies.

"Ah, my dear sir, with a queen some little formality is required. Court etiquette demands other language than that in which common-folk are addressed. Let me see if I cannot persuade her to show herself. 'Will your gracious majesty condescend to honor this company with your august presence?'"

The card at once comes up, but feet foremost.

"See sir," you cry, "my politeness has brought her out, but to show her anger at your want of courtesy in addressing her, she comes up feet foremost. We will see, however, whether we can remedy it."

You take the card and place it again in the pack with its feet still uppermost, but are careful to put it among the front cards, and not near the thread. A duplicate queen has previously been arranged among the prepared cards, and when, turning towards the pack, you say: "Now will your High Mightiness be condescending enough to throw a somersault—under cover of the other cards—and appear before us in a manner more becoming the dignity of your station," the duplicate card appears, and nine out of ten in the audience imagine that in some way to them unknown you have really caused the card to turn over in the pack.

Another very pretty effect is that of mending the card. When the cards are first drawn, you ask one gentleman if he will be sure to remember his card. Of course he will reply "Yes."

"Very well, sir," you say. "I've no doubt

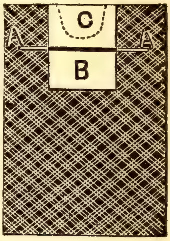
you think you will, but so many wonderful things are happening just now, that it is possible—understand me, sir, not probable, but merely possible—that you might even forget the card you drew. To guard against this I will tear a piece out of it, which I will give to you to hold." As you say this you tear a small semi-circular piece out of the top of the card and hand it to him. When the card appears from out of the pack the piece of course is wanting. You take it from the person who has it, and making a motion, as if throwing it towards the pack, the piece disappears from your hand, and at the same moment the torn card appears whole.

There are several ways of mending a card, each "magician" using that which he likes best, but the principle is the same in all, *i. e.*, a hinged piece, working on a spring and flying into its place at the right moment.

"Psha!" I think one of my young friends says, "there's another spring. I hate springs." But springs are very good in their place and in no place are they more useful than in mechanical tricks. The only trouble is, that in most descriptions of conjuring tricks, they are pressed into service when not absolutely necessary. If a trick is being explained the working of which the writer does not very clearly understand himself, the first thing you know, up pops a spring in your face. They are so handy, they save a deal of trouble and explanation.

But the spring in the "mended card" is a very simple thing, being nothing more than a piece of india-rubber, one of those long strings such as elastic cloth is made with.

I will begin, however, as I ought, and describe the whole arrangement. Take a duplicate of the card which you intend to force, and from one end of it, at about the centre, tear out a semi-circular piece. Next cut out a square piece of bristol-board, somewhat larger than the piece torn out, and on this paste the torn piece. When dry fit the piece back in the card and paste the lower part of the bristol-board to the back of the card. Fasten a piece of elastic cord to the back of the card in such a way that it crosses the piece of bristol-board. In the annexed illustration, which represents the back of the card, B is the piece of bristol-board, C the piece torn from the card, shown by dotted lines, as it is on the other side of the bristol-board, and A A the points at which the ends of elastic are fastened. Suppose, now you bend back the piece B until it lies against the back of the card; so long as it is held it will stay there, but the moment it is released, the action of the "spring" will force it in its place again. When about to exhibit the trick take the card, press back the piece B until perfectly flat, and push the card down into the pack (carrying the thread with it). If the thread is pulled so as to draw the card partly out, it will appear without the piece,



as the other cards will hold it back, but if drawn out a trifle further, until the piece is clear of the other, it will fly into its place and that so quickly, that the audience will not be able to see whence it comes.

The trick as I have described it, can only be done at the theatre, or if exhibited at a private soirée, the young magician will require to have part of the room set off for his stage, and not allow his audience to intrude therein. It may be arranged, however, so as to be shown under the very noses of the audience, and if the performer only has sufficient impudence it will not be detected. For this purpose we use a hair, instead of a thread. Get a dozen long black hairs from some lady friend and tie them together by the ends, until they form a string about a yard long.

The best knot for this purpose is that known as "the figure eight," and when neatly made is almost imperceptible. Arrange the cards in the same way as if for the thread, using the hair instead, and in place of having it carried off to the hands of an assistant, fasten the loose end by means of a bit of wax to an old-fashioned copper cent. Place your prepared cards on the table, and the cent at a little distance from them. On the same table have an ordinary glass goblet. After the cards have been drawn and replaced in the pack, return to the table and place them on top of the prepared cards. Take the goblet to the audience, and when they have examined it to their satisfaction, give it to the person whose card is to come up first. Go back to the table for your pack; pick up the cent with your right hand, and "palm" it, and with the same hand take up the pack. Approach the person who has the goblet and request him to hold it as high above his head as possible, "That all may see it," you say, but really that he may not see too much. Place the pack in the goblet, retaining the cent in

your hand. Rest your hand on your hip, or take hold of the edge of your coat. When you want the card to rise, turn the right side of your body very slightly, away from the goblet, which will, of course, pull the hair, and the card will come up.

As soon as it is fairly out of the pack, take it with your left hand and give it to the person who holds the goblet; beg him to examine it, and whilst his attention is engaged with it, you take the goblet and pass to the one whose card is next to come up. As your hair is now a trifle longer, you stand a little further off from him than from the first, but in every other respect you do the same as before. And so you go on until all the cards have arisen.

The object of fastening the end of the hair to a cent, is to save feeling for it, which you would otherwise have to do, as it is impossible to see it when lying on the table.

There need be no fear of the audience discovering the hair, as I have performed the trick very many times in a brilliantly lighted hall, and never been detected. You cannot, however, use the torn card when exhibiting the trick in this way.

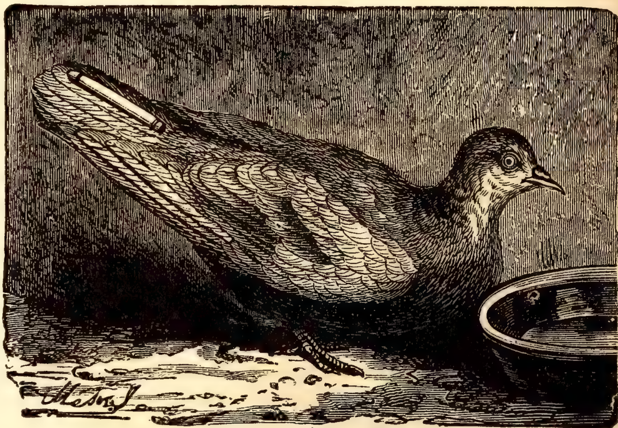
There remains but one thing more to explain in connection with this trick, and that is: how to make the audience draw the particular cards you want them to, so that they may correspond with those in the prepared pack. It is as easy as any part of the trick, but as the limits of my lesson are already reached, I shall have to defer that explanation until next month.

Microscopy.

The Microscope in War.

At first sight it seems strange that the microscope should find any direct employment in the conduct of warlike operations, but when we recollect the great importance of dispatches to the defenders of a besieged city and to their friends outside, there is no longer room for wonder. It was probably during the siege of Paris that the microscope was brought most extensively into use as an aid in transmitting intelligence.

Every reader of this journal has heard of the carrier pigeon, and knows that it is employed to carry messages from one place to another, but all are not aware, perhaps, that pigeons cannot be made to carry a message *away* from home; they can be used only for sending messages back from some place to which they have been carried from their own dove-cotes. Now during the siege of Paris it was easy for those who were confined in that city to escape by means of balloons, but it was impossible for those who were outside to get into the city. To convey information to the inhabitants,



Carrier Pigeon with Micro-Photograph.

those who escaped by balloons took with them carrier-pigeons, and these pigeons conveyed back the required information in the form of letters. That these letters might occupy as small a space as possible, they were first printed in large sheets, and these sheets were then photographed, but on so small a scale that the letters were utterly invisible to the naked eye. Indeed so small were they that a copy of a twenty-four page New York Sunday *Herald* might have been easily packed in a crow quill. These photographs were then rolled up, enclosed in a quill, and fastened to the bird in the manner shown in the engraving. When the bird reached its former home in Paris it was caught, the quill removed, and the photograph read by means of a good microscope.

The Social Science Association of Boston publishes the startling, if true, statement that several mills in New England are grinding white stone into powder, to be used in adulterating sugar, soda, and flour.

The Heavens for January.

BY BERLIN H. WRIGHT.

MERCURY will be brightest as a morning star, Jan. 16-19, rising Jan. 17, at 5h. 49m. morning—1h. 32m. before sunrise, and about the time twilight begins. He enters the constellation Sagittarius, the Archer, Jan. 14, and on the 17th, when brightest, will be 3° in that constellation; being in the center of the Milky Way and 3° north of the fourth magnitude star in the end of the handle of the Milkmaid's Dipper. He will be 3° north of the Moon Jan. 20, and set about 2½° south of the sunset point.

VENUS is still unfavorably situated for observation; setting Jan. 12, 5h. 31m. eve., and Jan. 31, 6h. 18m. eve. She will be in the constellation Capricornus, the Goat, throughout the month, entering Aquarius Feb. 2. The first magnitude star, Fomalhaut lies 16° south and 15° east of her. Her disc will be considerably smaller than at other times, as she is in the farther part of her orbit from the earth, and also farthest from the sun. Her phase will be gibbous, similar to the Moon's, when a few days from the full. She will be 2½° south of the Moon Jan. 23, and very close to Jupiter the same evening.

MARS is a morning star, and is moving eastward among the stars of the constellation Scorpio, being about 8° north east of the "fiery red" first magnitude star Antares the first of the month. He rises as follows:

Jan. 10, 4h. 46m. morn., Jan. 20, 4h. 40m. morn., and Jan. 30, 4h. 33m. morn. He will be 3¾° north of the Moon Jan. 19, in the morning.

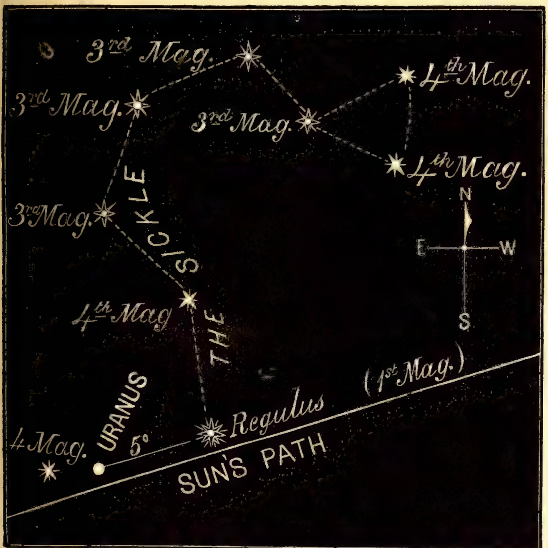
JUPITER will be about 2° south of the Moon Jan. 23. He sets as follows: Jan. 10, 6h. 38m. eve., Jan. 20, 6h. 12m. eve., and Jan. 30, 5h. 44m. eve. He is too near the sun to be viewed satisfactorily.

SATURN will be 1° south of the Moon Jan. 27. On the 26th, he will be exactly upon the equinoctial colure, from which right ascension (corresponding to terrestrial longitude) is reckoned, eastward, and 2½° south of the Earth's path, the ecliptic, which is also the sun's apparent path. He sets as follows: Jan. 10, 10h. 25m. eve., Jan. 20, 9h. 50m. eve., Jan. 30, 9h. 15m. eve. A good four-inch telescope will show all the satellites, when at their greatest angular distance east or west of the planet.

URANUS passes the meridian as follows:

Jan. 5, 3h. 26m. morn.	Jan. 20, 2h. 26m. morn.
" 10, 3h. 6m. morn.	" 25, 2h. 1m. morn.
" 15, 2h. 46m. morn.	" 30, 1h. 41m. morn.

As he is nearly at greatest brilliancy, we give in the annexed figure his position with respect to the surrounding stars. A person of good eyesight can see him, by thus knowing his exact position, without the aid of an opera glass or telescope. The observer must, however, choose a moonless night or at least when the moon is very distant from the planet. Jan. 7–15 and Feb. 3-11, will be unfavorable for observing, because of the nearness and brightness of the Moon.



The Heavens for January.

Before attempting to look for him, the eye should become accustomed to perfect darkness. It would be well for the observer to shut himself in a perfectly dark room for thirty minutes, keeping the eyes *wide open*, before making an observation, and in passing into the open air the eye should not be allowed to encounter artificial light. The Sickle is one of the most conspicuous figures in the heavens, and nearly every school-boy has traced its outline.

Neptune passes the meridian as follows: Jan 10, 7h. 0m. eve., Jan. 20, 6h. 21m. eve., Jan. 30, 5h. 42m. eve. (For figure showing his place among the stars, see YOUNG SCIENTIST for December, page 160.)

METEORS.—The following are the dates of the star-showers for January. Jan. 1–4, 18, showers of falling stars occur with more or less regularity upon these dates. It must be remembered that the earth may pass through these meteoric streams while it is day to us. In that case the inhabitants of the antipodes would witness the display. The radiant point of the last seems to be near the Northern Crown; of the first about 20° north of the same.

—There will be three eclipses this year; an annular eclipse of the Sun, Jan. 22; annular eclipse of the Sun, July 19; and partial eclipse of the Moon, Dec. 28. All of these will be invisible in North America.

THE

YOUNG SCIENTIST.

Published Monthly at 50 cents per year.

Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers the 12 cents postage which we have to pay on city addresses.

All COMMUNICATIONS should be addressed to

THE YOUNG SCIENTIST,
P. O. Box 4875. 176 Broadway, New York.

☞ For Club Rates, Premiums, etc., see PROSPECTUS.

Has Your Subscription Expired?

This number will be sent to all old subscribers, whether they have renewed or not. Succeeding numbers will be sent to those only who have been entered upon our books for 1879.

Our New Volume.

In commencing a new volume of the YOUNG SCIENTIST it may be well to take a calm view of past success and future prospects. After the first year the progress of every journal settles down into a steady gait, and it is not difficult to determine the extent to which vigorous effort is warranted.

Although our circulation is still very far from what we expect it to be ultimately, we feel sufficiently encouraged to warrant us in securing the very best matter and illustrations attainable for our pages. We can therefore promise our readers the very best articles that can be procured, and by a better arrangement of our matter and the use of new type we expect to give more than even the promised increase of four pages. We therefore have no hesitation in calling upon our friends to exert themselves for us, for we intend to exert ourselves most earnestly for them.

Careful examination will show that the present number contains as much matter as eighteen pages of the numbers issued last year—an increase of quite one-half. At the same time our new, clear type makes not only a more readable but a more beautiful page.

Our Trial Trip—Back Numbers.

IN offering four numbers as a trial trip at a price *less than the yearly rate,* our sole object is to give to those interested an opportunity to examine the journal more fully than can be done by the inspection of a single number. We do not propose to supply a file of the journal at these rates, and neither do we propose to furnish a year's numbers in free specimen copies. Our January number is intended to be a fair specimen of the general scope and character of the journal for 1879, and will be sent to all who desire a specimen and the numbers for January, February, March and April, will be sent to those who subscribe for a trial trip. Other single numbers may be had for six cents each, and the eight numbers following the April number will be sent for 35 cents.

We have on hand a few complete sets for 1878, which may still be had for 50 cents, in loose numbers. We have also a few volumes with wide margins, handsomely bound with gilt titles, price $1.00, postage ten cents extra. The numbers for 1878 were not stereotyped, and the number on hand is now quite small.

Our circulation is now so great that we feel not only warranted but compelled to stereotype the pages of the journal. Full sets and odd numbers for 1879 will therefore be always on hand.

Things that are Old.

That the world moves and that knowledge increases have passed into proverbs. Nevertheless it is the experience of every one who has watched the history of the arts, that real novelties are scarce. Occasionally we have a new discovery which leads to entirely novel practical applications, but on the other hand many of the things which are brought forward as new, and which prove intensely interesting, are really old. In proof of this we may note that the readers of one of the prominent mechanical journals in England, have for several weeks past been deeply interested in the curious experiment known as the "Pneumatic Paradox," a singularly interesting and wonderful puzzle which occupied the attention of

the readers of the old *Mechanic's Magazine* fifty years ago.

Individuals as well as the ages have their cycles of progress, and what is old to the man of fifty is new to the boy of fifteen. Too often, however, the man thinks that what is an old story to him must be well-known to the boy, and he therefore neglects to give the boy the benefit of his experience. And yet if the boy would attain to the knowledge possessed by the man, he must pass through just this experience or something very similar. The time spent in discussing these old things revived is not therefore by any means lost, and we shall never hesitate to bring forward an old experiment, provided it is a good one. The firing of a cannon with an icicle is older than most of our readers, but it is just as interesting to-day as when first brought forward.

Rustic Wall Ornaments.

We had moved from the city into the country and within a short distance from the house was a stretch of woods where the children spent most of their time after school hours, collecting ferns, lichens, mosses, old nests of birds, etc., so that a great accumulation of these odds and ends of nature were on hand to be made up for home adornment and presents.

One of these, a group consisting of ferns, and lichen-covered branches, with nest and birds, was so greatly admired, that I have drawn and engraved it for the benefit of the readers of the YOUNG SCIENTIST.

It consists of a shield of wood three-fourths of an inch thick, six and a half inches wide, and twelve inches high, to which small branches thickly covered with a natural growth of lichens were securely nailed. The center and largest branch extended well out from the front of the shield. The face of the shield, between the branches, was covered with a small fungus of a grey and brown color, that grows in masses on old stumps. These were well dried in an oven before they were glued on, after which they were touched up here and there with bright green wood mosses.

An old nest of a blue bird, containing five eggs, was fastened to the largest branch, and beside the nest was a carefully stuffed hen bird looking in at the eggs. Above the nest was perched a male bird in the act of singing.

Next came the disposing of the dried ferns. Knowing that after being out of the press a few weeks they curl up and look unsightly, and are also apt to fade, I prepared a colored wax stiffening, composed of the following materials : one quarter of a pound of bright yellow beeswax, and half a teaspoonful of Canada balsam. These, when melted together, were poured into a large plate, well heated, so as to keep the wax melted. To this was added two parts of ground gamboge, and one part of best Prussian blue, ground to a fine powder with a table knife.

These pigments require a deal of grinding in the hot wax before the transparent, light, sappy green so desirable in coating ferns is obtained. The coating or stiffening had to be done very carefully in the following manner: Taking two thicknesses of blotting paper or muslin, I placed between them some

Rustic Wall Ornament.

of the prepared wax : then they were ironed over with a moderately hot flat-iron, till the wax flowed freely through the upper muslin. A frond of fern is then laid on, and over this another piece of muslin, ironing again, and adding more wax till the leaf was well soaked and covered with wax, after which the fern was taken out, and found to be coated evenly, and not too thickly so as to look clumsy. In ironing the climbing ferns, each leaf had to be done separately, and was afterwards held before a fire to slightly soften the wax, when each leaf was bent and shaped so as not to look flat and unnatural, as when they came out of the drying press.

Only well seasoned and woody ferns can be used for this work ; all thin and delicate ferns, such as the maiden's hair, are useless. Another advantage this wax stiffening possesses, is that dry colors can be rubbed on just the same as in wax flower work, so that the leaves need not be all of one uniform green. In ironing, I avoided pressing on the mid-rib or stem of the fern for fear of breaking it, and thus destroying its natural support.

Over the fungi and between the branches, I fastened small fronds of fern with pins. Toward the

top of the shield a mass of large ferns was fastened with a feathery dried grass, introduced here and there, which produced a very graceful pleasing effect.

The climbing ferns were used for festooning the leafless branches. As a balancing point to the bird singing, I fastened a cocoon of the *Attacus Cecropia* with the moth above it, as though it had just come forth. A few brilliant insects stuck on here and there in the way of finishing touches, completed this grouping of bits of Nature's odds and ends. *A. W. Roberts.*

To Pour three Different Liquids out of one Vessel.

Conjurers generally perform this feat by means of a bottle divided into compartments, but the young chemist can easily do it with very little preparation. Take three tumblers, and into one pour a very little (three or four drops) of a strong solution of acetate of lead; into another, a solution of sulphate of copper, and into the third, a little tincture of iron. The quantities of these liquids may be so small that they will not be perceived by those to whom the trick is shown. Then provide a pitcher (preferably of glass, because it is transparent and shows that there is no trickery about it), and fill it with water, in which an eighth of an ounce of prussiate of potassa has been dissolved. On filling the tumblers out of this pitcher, one will be filled with white liquid resembling milk; a second with a blue liquid, and the third with a dark red liquid. To those who see it for the first time, this experiment is very striking. The explanation is simple. The prussiate of potash (potassic ferrocyanide), is decomposed in all three cases, and white, red and blue compounds formed with the lead, copper and iron respectively.

To fire a Cannon with an Icicle.

Load a small cannon very lightly with powder, and prime it well. On the priming lay a small piece of potassium. If the priming be now touched with an icicle or a moist stick, the potassium will take fire and fire off the cannon.

In handling potassium, be very careful not to touch it with moist fingers or anything damp, or it will certainly take fire and produce very serious burns. Hold it with a pair of forceps or tweezers, (such as accompany every sewing machine), lay it on dry blotting paper, and cut off what you want. A piece the size of a grain of mustard seed is large enough.

An Acoustic Experiment.

Let a wide glass tube, open at both ends, be taken, and in this a piece of fine wire gauze be pushed up some little distance. If the gauze be now heated to redness over an ordinary Bunsen burner, and then removed, it will shortly emit a shrill note, lasting from five to ten seconds. The experiment will be new to most of our readers, and has the merit of always going off.

Drawing Boards for Amateurs and Students.

The best kind of drawing board for amateurs and students, is made of good pine without cleats or cross-pieces. The end cross-pieces usually put on drawing-boards are very objectionable, on account of the unequal shrinkage of the body of the board with the grain of the wood running longitudinally, and the grain of the cross-pieces which run tranversely, or at right angles with the former, always leaving shoulders or projections on the edges of the board, that prevent the accurate use of the T square. The most convenient size for a board is 27 inches by 21. This takes half a sheet of double elephant drawing paper, which will be found the best size for ordinary work, the smaller sizes being too light for finished mechanical drawing. And it will be found that a board of this size, made out of clean, sound and well-seasoned pine, will stand without any cleats or cross-pieces. It should be left quite plain and neither oiled or varnished.

The most important point is that the sides should be parallel, and that one of the ends at least should be at perfect right angles to the sides. This end should be marked and always placed at the left hand, and it is of very little consequence about the other end. But it will be found that it is not such an easy matter to get the end and sides square as some people think. Ask the majority of carpenters to do it for you, and they will fail. You must either do it yourself, or watch and guide them while they do it.

The best way is first to make one end perfectly straight. Never mind its relation to the sides; get it perfectly straight, and when you have it so, never touch it afterwards, but keep it for a guide or base line. The end being straight, make one side square with it. To find out whether it is square or not, you must not rely upon common iron squares, but you must test it with your T drawing square. And by the way, it is of no consequence whether the blade of this square is square with the stock or not; if the blade and stock are both straight, this is all that is necessary. For if you think a little, you will see that the angles in your drawing depend upon the board and not on the square. To test the board therefore, apply your T square to the side you are working on, draw a line across the right-hand end within an inch of the edge. Then apply the square to the left end, and draw a line across the center of the board. Try, by the ordinary rules of practical geometry, whether or not these lines are at right angles. If so your work is done; if they vary a hairsbreadth, plane off a little from the side, and try and bring them true.

Drawing paper should be mounted, for finished drawings (colored or shaded), but for common work it is more convenient to fasten it to the board with drawing pins or thumb tacks. Hence the necessity of having the board of soft wood; if otherwise, the pins will be blunted, bent, and difficult to press in and draw from the board; this operation can generally be done by the thumb nail.

PRACTICAL NOTES.

Ink.—In the recipes generally given for making ink, it is recommended to *boil* the ingredients. This is a very serious mistake. It should always be made with cold water. By this latter process, more time is of course necessary to make it; but then the ink is very superior, and entirely free from extractive matter which has no inky quality, and which only tends to clog the pen and to turn the ink ropy and mouldy. Take gallnuts, broken, one pound; sulphate of iron, half a pound ; gum acacia and sugar candy, of each a quarter of a pound; water, three quarts. Place the whole of these ingredients in a vessel where they can be agitated once a day ; after standing for a fortnight or three weeks the ink is ready for use. Logwood and similar materials, are often advised to be used in conjunction with the gallnuts, but they serve no good purpose unless it be to make a cheaper article which fades rapidly.

Clay for Modelling and Terra Cotta.—In answer to a correspondent, the *Druggist's Circular* gives the following information on this subject: Any kind of good plastic clay will answer, and it is of no consequence if it contains iron even in large proportions. Only it must be freed from stones and coarse sand by means of elutriation, and be well kneaded together to insure homogeneousness. A mixture of glycerine and water was at one time proposed to moisten modelling clay, so as to avoid the necessity of constantly wetting the models, but it is said that the process is unsatisfactory, as the clay on drying allows the glycerine to escape in drops. In technical parlance, it "sweats out." For *terra cotta,* clay containing too much iron is undesirable because, on baking, it assumes a glaring brick-red color. But a moderate proportion of the metal imparts to the finished objects a very pleasing color. Of course, glycerine is quite out of place in clay that is to be baked.

Varnishing Wood.—A good surface may be produced on unpainted wood by the following treatment: glass-paper the wood thoroughly as for French polishing, size it, and lay on a coat of varnish, very thin, with a piece of sponge or wadding covered with a piece of linen rag. When dry, rub down with pumice dust, and apply a second coat of varnish. Three or four coats should produce a surface almost equal to French polish, if the varnish is good and the pumice dust be well applied between each coat. The use of a sponge or wadding instead of a brush, aids in preventing the streaky appearance usually caused by a brush in the hands of an unskilled person.—*Artizan.*

Metallic Soap for Canvas.—The following is highly recommended as a cheap and simple process for coating canvas for wagon tops, tents, awnings, etc. It renders it impermeable to moisture, without making it stiff and liable to break. Soft soap is to be dissolved in hot water, and a solution of sulphate of iron added. The sulphuric acid combines with the potash of the soap, and the oxide of iron is precipitated with the fatty acid as insoluble iron soap. This is washed and dried, and mixed with linseed oil. The soap prevents the oil from getting hard and cracking, and at the same time water has no effect on it.

Tracing Patterns.—When a few duplicates of patterns for embroidery are required, they may be very easily made by hand as follows :

The drawing is made upon paper; then lay the drawing upon an even cloth, and perforate all the lines with a fine needle, close and even. Then take finely powdered charcoal, three parts, resin one part in fine powder; mix and tie it in a piece of porous calico, so that it forms a dusting bag. Lay the perforated drawing upon your material, hold down with one hand, rub the dusting-bag over the drawing; the dust will fall through the holes and form the drawing on the material. Remove the paper drawing, lay blotting-paper over the dust pattern, and go over it with a warm flatting iron. The heat will melt the resin and fix the drawing on the material.

Fire Kindlers.—A writer in the *New England Farmer* says that pine needles make the best fire kindlers he has ever used. In northern regions they may be gathered in the woods in any quantity, and if kept under cover and dry, they are far ahead of shavings, whittlings, etc. As they contain a very large proportion of resin, the suggestion deserves attention.

Superior Paste.—It is said that a paste made of seven parts of gum tragacanth and one part of gum arabic, with a few drops of oil of cloves, or diluted carbolic acid, will be found very reliable. It adheres strongly and does not turn sour like book-binder's paste, which is made of flour.

Soldering Fluid.—It is said that a solution of phosphoric acid in alcohol makes an excellent soldering fluid, which has some advantages over chloride of zinc.

BOOK NOTICES.

The Young Chemist.—A book of Laboratory Work for Beginners, By John H. Appleton, A. M., Professor of Chemistry in Brown University. Second Edition. Philadelphia : Cowperthwait & Co.

The importance of experimental illustration of the scientific facts brought to the attention of pupils, has been long acknowledged by all educators of intelligence. One good experiment is worth an hour's talk, and a single glance through a microscope at a good preparation is worth pages of description. Professor Appleton has therefore done a good work in endeavoring to smooth the path of teachers and pupils in this direction, but we wish he had brought the experiments within the reach of a wider class than he has done. While there are many valuable suggestions in the book, there are many points which might have been simplified, and although he says himself that one objection to the introduction of the experimental method is the cost of supplies, his apparatus is not always as cheap as it might be without reducing its efficiency. Side neck flasks and test tubes are very good, but it is not every teacher that can make them, and they can be procured only from dealers in large cities. Common test tubes, and what is called quill tubing, may be had from any druggist, and the teacher who cannot make gas-apparatus out of these and a good cork, had better not try to experiment. So, too, the leaden saucer used for preparing fluorine (page 30), must be procured from a dealer; while a saucer, equally good, might be made by the teacher himself, if a figure of it had been given.

The book is evidently intended for beginners, but does not always give them needed caution. The experiment under section 43, page 28, *might* be a dangerous one. It would have been well had the author been more explicit.

We welcome the book as a step in the right direction, but trust that the author will take an early opportunity to improve it.

Exchanges.

Yearly subscribers to the YOUNG SCIENTIST have the privilege of inserting three exchanges (or one exchange three times) during the year. This privilege is strictly confined to *exchanges; buying and selling* must be carried on in the advertising columns, where the charge is 30 cents per line. Each exchange is limited to thirty words, making about four lines, and in order to receive attention must be written on a slip of paper by itself. We file all letters received and have no time for copying out exchanges and queries.

As we desire to make the journal of the utmost value to *all* and not merely to serve the interests of individuals, we shall strictly adhere to these rules, which are certainly liberal, giving as they do advertising to the value of $3.60 free to each subscriber.

Groff's Model Suburban Architecture wanted in exchange for Nicoll's Railway Building, Templeton's Practical Examination of Steam and Steam Engine, and Colburn's Locomotive Engine. All entirely new. F. H. Jackson, Angelica, N. Y.

Wanted, a small turning lathe, state what is wanted in exchange. Ralph A. Pillsbury, P. O. box 555, Belfast, Me.

To exchange, beautiful rose, milk, greasy and smoky quartz, graphic granite, orthoclase, etc., for aboriginal relics, coins, or other minerals. Prof. C. L. R. Wheeler, Bedford, N. Y.

A collection of invertebrate fossils, accurately labeled and worth $225, to exchange for good microscope. The instrument must be of modern make, and in first-class condition. S. Calvin, Iowa City, Iowa.

A collection of foreign and dept. stamps, or a large collection of bird eggs of the Southern States, for a set of drawing instruments or books on plain and ornamental penmanship. Address Q. R. S., Mt. Pleasant, Washington, D. C.

Wanted almost anything in exchange for a complete set of cabinet maker's tools. The chest alone is worth twenty-five dollars. Address Mr. Clark, P. O. box 37, Brooklyn, N. Y.

For exchange, two good dial telegraph instruments, and two good Morse telegraph instruments, for printing press or bracket saw. James Scott, 20 Patchen ave, Brooklyn.

A card printer, type and cards worth $1.50, and the book "His own Master" will exchange separately or all together, books, or offers. Geo. R. Simpson, Janesville, Iowa.

A stationary cylinder steam engine, or hardware goods in exchange for an electric call bell. L. J. Otis, 973 Prairie Ave., Chicago, Ill.

Wanted for a good Gundlach No. 4 (¼) Objective, a 1½ or 2 inch Objective of wide angle. C. Onderdonk, Brooksburg box, Madison, Ind.

A spy glass costing five dollars, to exchange for a companion scroll saw and turning lathe in good condition. John Buck, Brazil, Clay Co. Ind.

Forty good photo-lantern slides, plain and colored, for a good printing press and outfit; or a small screw cutting lathe; or first class microscopic objectives, or offers. Wm. R. Brooks, Phelps, N. Y.

Wanted, a small rifle, in good order, bore 22-100, for a telegraphic key and sounder, instruments are made of brass finely wrought, mounted on a japaned iron base. Louis E. P. Smith, 6 Alpine st, Boston, Mass.

Ferns, mounted or unmounted, for Northern species of same. List of those on hand and those wanted sent on application. Maj. R. H. Wildberger, Ky. Mil. Inst., Farmdale, Ky.

Two good business lots, central, in Ellsworth, Kan, for good microscope, accessories and books, chemical balance, or gold watch. Wm. Zimmerman, 114 Dearborn st, Chicago, Ill.

To exchange, a collection of 500 rare stamps, with book which cost $1.50. The whole worth about $7.00. State offers. Albert N. Webster, 106 South Park ave, Chicago, Ill.

Hinkley knitting machine, worth $40, for a watch or breach loading shot gun, Harry Holden, Black Earth, Dane Co. Wisconsin.

One dozen (assorted) mounted objects for microscope, cost $2.50 (By J. W. Queen & Co.) for useful books on any subjects, or old U. S. coins. W. M. Stribling, P. O. box 350, Circleville, Pickaway Co, Ohio.

Cabinet mineral specimens, for Masonic publications, or other instructive books. Light reading not wanted. J. P. Clough, Junction P. O., Lemhi Co. Idaho.

Swiss watch lathe, brass, steel shaft and box, cost $25. Also a gear cutting lathe nearly complete. Exchange for minerals, microscopic slides and books. H. A. Cutting, Lunenburg, Vt.

Twelve dollars worth of parlor tricks, very best make, in exchange for a good microscope or a scroll saw with lathe attachment, of equal value. Prof. C. H. Houghton, Middleboro, Mass.

Book on magic, cost $2.50, for back numbers Young Scientist, and foreign stamps. Omega, Post Warrensburg, Mo.

Wanted, Parrishes Pharmacy and chemicals. State what is wanted in exchange. C. O. K., 1520 Fairmount Ave, Phila.

Stereoscopic views of New York city and vicinity, in exchange for fossils from the Western states and territories. T. P. Wendover, P. O. box 1862, N. Y. city.

Chemical apparatus or balance, spy glass or saw wanted, in exchange for novelty printing press, with sixty fonts of type. Alex, 151 East 33d st, N. Y.

Microscope worth $7.00, and cabinet with forty good slides; for better instruction or other educational apparatus. Particulars on application. Arthur Hobart, Penn Yan, N. Y.

Wanted a copy of Bourne's Treatise on the Steam Engine, for a full set (7 vols. bound) of Technologist, cost $19.25. W. J. Allen, 256 Twenty-second st, Bkyn.

Wanted, a three wheel "velocipede" large size, state what is wanted in exchange. Peter J. Murray, box 743 Wilkesbarre, Pa.

To exchange, one Bunsen and two Smee batteries; for books on electro-metallurgy or quantative or qualitative analysis. A. W. Palmer, care of Watch Co. Springfield, Ill.

A pistol in good order, cost $3.00, in exchange for an electric bell. A. W. Honywill, 217 Cabot st, Boston, Mass.

Collection of over 500 rare stamps, including Ecuador Cape of Good Hope, Barbadoes, Honduras, etc., in exchange for microscope, minerals, or scientific publications. Jas. G. Kitchell, 345 Race st, Cincinnati.

Music box, printing press, cost $35, and complete outfit for cutting stencil plate for marking clothing, cost $25, for boiler large enough for ¼ horse power. Geo. A. Battles, Westminster, Mass.

Three-quarter portrait camera tube, with box and tablets all new; for books on science, medicine, history, or travel, or microscopic slides. J. S. Mason, Medina, Ohio.

Wanted, a printing press or set of draughting instruments for a C cornet (worth $30.00) or Queen's Universal Household Microscope and accessories. G. E. T., Box 475, Westboro, Mass.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, FEBRUARY, 1879. NO. 2.

A Tale of a Tub.

THIRTY years must have passed since I set up my first aquarium. I had always a special fondness for birds, flowers, fishes and insects. To me a snake was as wonderful and beautiful as a golden carp or goldfish, as they are commonly called. And as at this time I was put in charge of the cows, to take them to the woods, watch them all day and return them at night, I was happy beyond all boys.

The cows were given fresh water every evening from a half butter tub, that had been in use for this purpose, for several years. One day I fell desperately in love with this tub, and I determined to possess it at any cost,—it was so beautifully moss-grown outside, and inside it was lined with what seemed to me the finest of velvet or plush, of a beautiful green color, only the nap was longer. I struck a bargain with my father, which was to the effect that I was to weed and thin out the long carrot bed, and the tub was then to pass into my possession. In due time I accomplish'd my task and the tub was mine. Now for this beautiful tub and what became of it.

Instinct (for it could scarcely be called reason) directed me to place it under a grape vine, where it obtained the same amount of light to which it had been accustomed when standing in the cow's yard. I then filled it with water and placed in it eight fresh-water minnows, of about three and half inches in length.

Every day for a month, I fed them on angle worms cut up, and they throve amazingly. But one day I forgot all about the tub and the fish, nor did I think of them again for some two months, till one day when looking for a pet tortoise that had strayed away, I was greatly surprised to find my minnows all alive and as plump and frisky as ever. So far as I could see, but little change had taken place except that the nap on the green velvet had grown longer. I was thoroughly mystified. How had the fish lived in the same water so long without its being changed? How had they lived so long without food? I was still more astonished, however, when, my conscience smiting me for leaving them to starve, I offered them a bountiful meal of tenderest angle worms, and they

didn't seem at all delighted, but turned up their noses, so to speak, at the delicacies offered them! I could not make it out, and it was of no use to ask any of my friends about it, for they took no interest in my "pollywog" collections, as they called them. So I was left to my own conclusions, and child-like they were.

I had been reading about fairies and fairy lore, and had become greatly interested in the accounts of the curious fairy circles that the Irish people reverence so much. So I made up my mind that in the woods or neighboring fields there existed a fairy circle. The fairies thinking well of me, because I thought well of the birds, flowers and insects, had, during my absence, taken care of my tub of fish. And in truth some wonderful and silent powers combining together had been the means of saving my fish, as I found out in after years. In this, my first aquarium, there was a perfect balance of the three great powers—sunlight, oxygen, and carbonic acid gas, acting in harmony with the animal and plant life present. I had thus established one of the most perfect self-sustaining aquariums I have ever possessed.

The philosophy of a self-sustaining aquarium is very simple when once understood. Its laws can never be changed, turned aside or gained by short cuts; and this tub aquarium will give us every rule that is required to run a self-supporting aquarium successfully.

The proportions of the tub, seventeen inches across the top (inner measurement) and eight inches deep, was excellent for exposing a large surface of the water to the atmosphere, thereby enabling the water to absorb oxygen from the atmosphere. The depth of water was just right to allow sufficient light to pass into all parts of the tub, for the growth of the plants, and the situation was such that the sunlight was not in excess, so as to overheat the water. These were three very important conditions gained at the start.

The green velvet-like substance that lined the tub, is one of the very best oxygenating plants known for an aquarium, and the number of fish was rather under the proportion that could be sustained by the same amount of water and plant life.

Without the green velvety lining, which consisted of a plant known as conferva, and which throws off large quantities of oxygen, the fish could not have existed in the tub over a week, and would have shown great distress, hugging the surface water for absorbed oxygen and breathing in air from above the surface of the water, till their lungs became diseased and in course of time, sickened and died.

To prove that this conferva does produce oxygen in large quantities, take the fish out of the tub and place it in strong sunlight, to stimulate the conferva to grow and breathe more rapidly. In an hour's time a froth will be seen forming on the surface of the water and adhering to the side of the tub, and a slight hissing noise will be heard. Looking very closely into the water, strings of what seem like minute silvery beads may be seen streaming from the conferva. These bead-like streams are oxygen gas thrown off by the conferva in the act of breathing. The froth on the top is an accumulation of these beads or bubbles. The hissing noise is the bursting of the bubbles of oxygen—all going to prove that the water is thoroughly charged.

If the reader should wish to prove that this gas is oxygen, it may be easily done by scraping a little of the conferva off the side of the tub, and performing with it the curious and interesting experiment described in the YOUNG SCIENTIST for August, 1878.

All animals breathe this oxygen, and cannot exist without it. As the minnows by opening and shutting their mouths cause the water to pass through their gills (which are their lungs) the oxygen held in suspension in the water, comes in contact with the carbon of their blood, and forms carbonic acid gas, which is poisonous to animal life.

As this gas is very easily dissolved in water it does not readily pass off in bubbles, but the water becomes so charged with it that if there was no provision made by nature for getting rid of this gas, all the fish and other aquatic animals would die. But strange as it may seem, if it were not for this gas, so poisonous to animals, all our beautiful flowers, trees, and aquatic plants would perish. It is this carbonic acid gas that the conferva utilizes in breathing through the stonata or lungs, exhaling that which is of no service to it (oxygen) but which the fish need to live on. And as it goes on, day and night, the plants performing silently miracles of work for their friends the fishes, and the fishes breathing out bountifully food for their neighbors the flora. How did the fish live without food?

They did not; Nature supplied them with the choicest diet. Over the tub grew a grapevine; on the leaves of the vine, the cane, the

fruit and the very tendrils, swarmed myriads of creeping things, flocks of aphides tended by their herdsmen the ants, vine sappers, lady bugs, crickets, etc. Was it not the easiest thing in the world for some of them to tumble into the tub? Then there were thousands of anxious mother mosquitoes looking for just such a watery spot on which to construct and launch forth their egg boats; could minnows ask for finer food than fresh laid mosquito eggs? And it is not improbable that a mosquito herself would sometimes be gobbled up as she rested on the water, in the act of constructing her egg boats. As for the sun, he shone on the tub one hour every morning, which was sufficient for so confined and small a body of water. The morning sun is always best, the rays are not so direct and ardent.

The great mistake in nearly all aquaria is that there is too much exposure of the water to the action of light, by which the spores of minute vegetable organisms contained in the water are developed in immense quantities by the heat rays of sunlight, till the water assumes an opaque greenish color, which can be overcome only by darkening down the tanks, or introducing snails and other animals that feed on this vegetable growth.

This tub was like a pond with its bottom and sides—not like the ill-constructed aquaria of the present day, with light penetrating the water from top, sides and ends, blinding the fish and stimulating the plants, till they spindle away into floating masses of decay. Another advantage about this tub aquarium was, that it was constructed of wood—a non-conductor of heat. The majority of tanks now-a-days are constructed of iron and glass, which are excellent conductors of heat.

The conferva are plants of a low order known as cryptogams, because they do not produce flowers, and their fruit or seed-bearing organs are not easily discovered. Hence the term *cryptogam*, which literally means hidden or secret marriage. The spores are contained in all water except spring water, and are also frequently present in the atmosphere. It is slow of growth, seldom develops in a well-regulated tank till the second year, and requires from one to two hours' sunlight a day and low temperature of water. Goldfish, crayfish, suckers, caddis-worms, snails and some varieties of tadpoles will eat up the young growth as fast as it develops. None but purely carnivorous fish can be placed in the same tank without its being destroyed. Dealers do not have it on sale, nor do they cultivate it in their tanks, as they prefer plants of freer and more robust growth, that can be bunched.

This tub aquarium ran successfully for several months, till one day I overstocked it with animal life and thus unwittingly disturbed the balance of nature. The minnows died, the green was eaten up by snails, and I concluded that I had offended the fairies or they had moved away, which accounted for the death of all and every fish placed in the tub ever afterwards.

In course of time when I had gained a knowledge of the laws that govern aquaria, I established a more wonderful tub than this one, and of this I will tell in some future article.

A. W. ROBERTS.

Engraving on Wood. II.

BY SARAH E. FULLER.

IN retracing the outline so as to transfer the drawing from the paper to the block, the point should not be sharp enough to cut the tracing paper. Retrace carefully every line, and do not bear too hard or you will bruise the wood, but use pressure enough to make the marks of the soft pencil come off on the block. On removing the tracing paper, a delicate pencil drawing will be seen, sufficient of the soft pencil having adhered to the wood to make a distinct drawing. It is now necessary to use a hard pencil, the six H being most suitable. With this pencil go over every part of the outline on the wood, strengthening the weak lines, and correcting any slight irregularities that crept in while tracing and re-tracing. Sometimes a piece of tracing paper, one side of which has been rubbed with red lead, is laid with the red side next to the block, between the block and the tracing. On tracing over this, the delicate drawing made on the wood will be red, and then can be drawn over in the same manner as the lead pencil tracing. This method is convenient when there are many lines, and they are close together.

When the outline is completed, and it is desired to put in the shading, this may be done with the pencil if the shades are light, and made up of lines crossing each other, making what we technically call "fac-simile" work. But if the shades are in "tints," that is, made up of even or graduated lines, it is usual to "wash" in the tints with India ink—the light

tints being put in first, and the darker ones made by repeated washes. After the tints are finished, complete the design by retouching where needed with the hard pencil; put in a few lines to suggest the direction in which the lines of the tints are to be cut, but it is not necessary to put in every line to be cut, except in the class of engravings named above.

To illustrate what we have just told you, we want you to examine the accompanying engraving of a flower. The sketch of this being on paper, we will remind you to trace all the outlines, that is, the edges of the leaves, flowers and stems, the stamens and veins in the leaves, and notice how some of the petals are turned over. When you have traced the picture on the wood in the way we have just described, proceed to "wash" in the tints. You need a cake or stick of India ink. On a small plate or saucer, with a few drops of water, rub a little India ink, using your judgment about the amount you require. Add water to make the ink pale enough for the light tint on the petals. With your brush moderately wet, put in this tint, being careful to leave the white places. Wash over the leaves and stems in every part except where it is quite white. When this first wash is dry, put on a second one, in the darker parts, leaving the light untouched, and a third or fourth wash in the darkest of all. You need to be very careful in making these washes, that you do not rub out the lines you traced. And probably with your best care, it will be necessary to pencil many of them over after you have finished washing the tints in. When you have corrected all the pencil lines, your drawing is done. The numberless fine lines that represent the tints are cut with the engraving tools, which cut out the white places between the lines you see printed, and stopping whenever other lines cross them. We have now told you how to make the drawing on the wood. We will next tell you how to engrave the drawing you have made.

Precision in Weighing.—The balance is now so perfect that according to Herr Jolly, weights of 1 kilogramme ($2\frac{1}{5}$ lbs.) may be compared to within the one-thousandth of a milligramme, or .0000154 grain.

Drawing Lessons. II.

BY JOHN CLARK CENTER.

We hold that as a factor of Education in almost all the practical departments of Commerce, Science and Art, the power to delineate any object or idea, is indispensable. The Engineer, the Builder, the Mechanic, the

Merchant, the Scientist, etc., each in his department, depends upon it to facilitate his progress, or to publish to the world his inventions or wares. For by a well-executed illustration the mind can comprehend at a glance, what a volume of words could not express.

Who can acquire this power of Drawing? Every one in the degree of his mechanical ability, and by perseverance in overcoming a few apparent difficulties, which we will endeavor to carry the student over. A fair degree of skill may be attained by at least ninety out of every hundred.

Now what is Drawing?

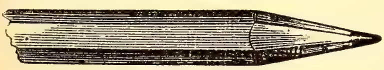
It is the method of combining straight and curved lines with proper adjustment of lights and shades, on a plane surface, so that any object or combination of objects may be repre-

sented; and thus we are enabled to reproduce to the eye and intelligence the form and general character of the subjects under consideration. The first step therefore must be to study the character of those lines and curves, lights and shades, which by acquired skill can produce such splendid results.

The development of this power involves the training and education of the eye, the mind and the hand, to act in unison. Systematic exercises for this purpose must therefore be carefully, faithfully and patiently persevered in, until this faculty be acquired. The judgment must also be able to approximate, independent of mechanical means, relative proportions, equal divisions of lines, perpendicular and horizontal relations; the nature and combination of peculiar curves, all of which by judicious handling, give the outlines of objects. These efforts may be tested by the rule, the compass and the square, to ascertain how near they come to the truth. But the *sine qua non* of success, is to acquire, as an instinct, independence and self-reliance.

To some this may appear difficult, and to many it may be really so, but perseverance will overcome, these difficulties will vanish, and the dawn of new power will richly repay and strengthen the aspirant.

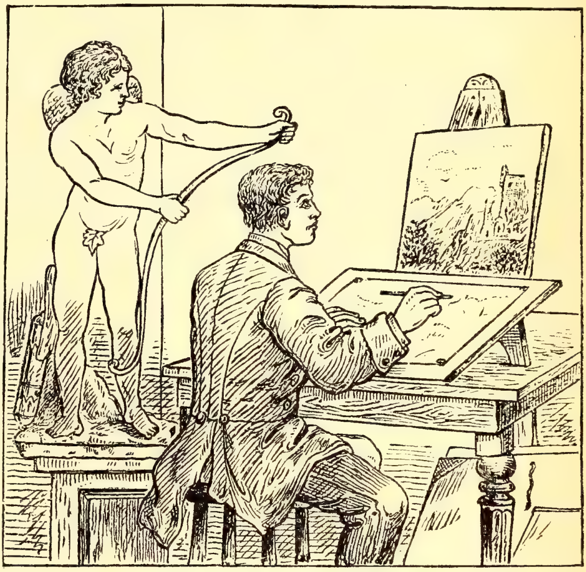
Provide yourself with a supply of paper for first exercise practice, get the cheapest you can find (unfinished brown is good); do not imply by this that your efforts are to be of a like cheap and common order; but *economy* in this matter will be the most useful lesson you can learn, for with many the desire to learn is frustrated by the extravagance of teachers, who require the very best and most expensive materials, which is not necessary in preliminary practice and study.



For *pencils* No. 2 Faber's are the best; these can always be depended on. To sharpen the pencil for exercises at this stage, do not get too sharp a point, as the nature of the work does not require it.

And now before we make a start, as we cannot superintend you in person, we must say a few words as to the best position for comfort and freedom of action. Many fail in not giving due importance to this point.

Procure a board say 24 by 18 inches, many of our readers can make one for themselves. Let it be smooth and square, place it on any ordinary table at an inclination of about 25°. This



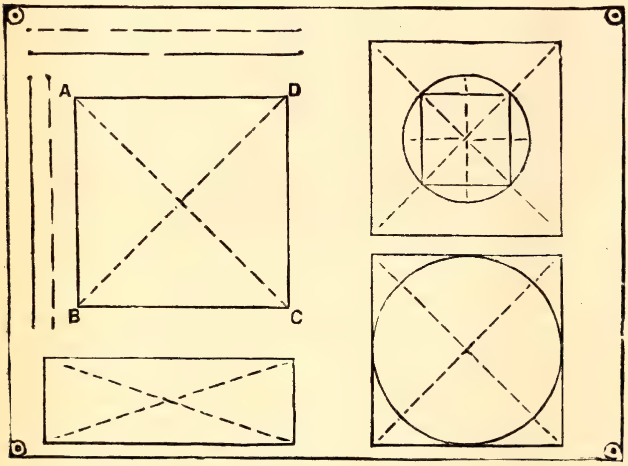
can easily be done by placing one or two books under one end of it.

Then place the body so that the greatest freedom can be maintained for the greatest length of time. We, in our usual work, can sit so, working on the most intricate and difficult drawings for ten hours a day, and every day at that, without any great fatigue. But we would not recommend beginners to sit more than one hour at a time, as the apparently dry exercise is liable to become wearisome, and induce carelessness. Carelessness must be avoided, in fact must have no part in any endeavor. Having secured your square sheet of paper on your board, be careful to place it so that it will be parallel with the four edges of the board; as this will be the only guide you will have to train the hand and eye in making perpendicular and horizontal lines. Take the pencil in the hand with a very free hold; do not draw from the wrist, but let the arm have an easy motion from the left to the right; avoid all stiffness. Now first let us practice on horizontal lines.

In the accompanying engraving we have endeavored to show all these points so that they will be easily understood.

Place by the eye on the upper left hand corner of your paper, two dots, say two inches apart (thus learn to judge measurement); and be careful that they are at equal distances from the upper edge of the paper. Then as a straight line is that which lies evenly between two points, join them from left to right by broken motions at first, as you will find this easier than in one continuous line. The perpendicular lines are to be treated in the same manner, they are to be drawn from the top downwards. The union of these two will give us a right angle.

By joining these two by an oblique line, we have a triangle A B C, and by carrying another line from A parallel to B C, of the same length to D, and then joining D C, we have a square; join D C and we have the diagonals of the square. This must be fully mastered, and you must be careful to test and try your work not only with the eye, but by measurements, as an error in this stage of a drawing would throw the whole drawing out of proportion. This you will see, is the key to any number of designs which may be contained in the square.



Again, by using the dotted lines as in the next example, the circle can be constructed in easy sections, and within the circle, all the possibilities of design which it may contain. We close this introductory lesson with an earnest appeal to our young readers to make themselves masters of these important exercises, not by merely drawing them once or twice, but making them part of themselves. In our next lesson we will show those who faithfully work out these exercises that they can do more than they imagine they can. For

> "By slow degrees to noble Art we rise,
> But lo! how grand to gain the glorious prize."

How to Make a Good Pantagraph.

BY WALTER W. SCOTT.

AMONG the instruments for reducing or enlarging drawings, the pantagraph, when accurately made, certainly takes the first place. Since the value of the pantagraph depends upon its accuracy and the absence of all lost motion at the joints, it is necessarily a costly instrument and seldom finds its way into the hands of the young, except in a very crude form. Now I will show how a very good instrument of this kind can be manufactured by any boy of intelligence, who has a little practice in the handling of carpenters' tools. By reference to the accompanying illustration it will be seen that the instrument consists of four parts, resembling rulers jointed together at their extremities, and two sliding carriages, having provision on their under sides for holding a pencil, while they are provided with clamping screws to hold them in their place.

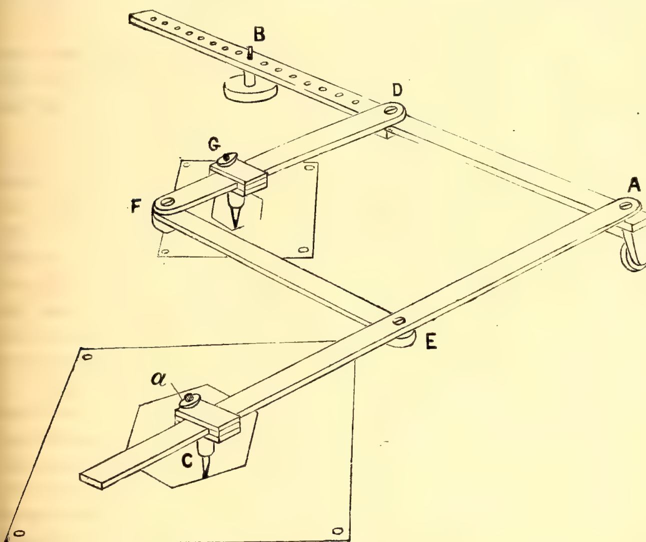
The pieces AB and AC are each two feet four inches long, from the centre of the screw at A, to the extreme end, one inch wide and one-quarter inch thick. The distances center to center AD, AE, FD, FE, are equal, being twelve and a half inches. All the joints of the instrument are made with one inch screws, and small blocks of hard wood, one inch by one inch, by half-inch thick, are glued under each joint to form a good hold for the points of the screws.

The fulcrum B is a leaden weight four inches diameter, and about one inch thick, having a wooden stem in it, so that it measures two and a quarter inches from the under side of the lead to the top of the wooden stem. A stout needle or short piece of wire, is driven into the top of the stem for the instrument to turn on. The holes in the piece AB at B, are about half an inch apart, and of such a size as to slip over the wire on the fulcrum easily.

The pencil used must be rather hard, say an

H, or No. 4, and must be nicely pointed on a file or piece of sand-paper.

The sliding carriages G and C are made of two pieces of black walnut, 2 in. × $1\frac{1}{4}$ in × $\frac{1}{8}$ in. thick, such as is used for scroll sawing, and two pieces $\frac{1}{2}$ in. × $\frac{1}{4}$ in. × $1\frac{1}{4}$ in. long; the small pieces are glued between the ends of the large pieces so as to make a block, with a hole 1 in. by $\frac{1}{4}$ in. (the size of the rulers), running through it. The pieces AC and DF must now be slightly reduced so as to slide easily, but not too freely, through the holes in the carriages. Two ordinary cotton spools with one end of each sawed off square, just where the bevel ends and the straight part, on which the cotton is wound,



commences. One of these spools must now be glued to the centre of one of the thin sides of each carriage, and the opposite side must be cut through one of the joints where it is glued to the $\frac{1}{2}$ in. × $\frac{1}{4}$ in. × $1\frac{1}{4}$ in. piece, with a thin saw, so that when that end is pinched together it will bind on the ruler, where before it slid easily. The clamping screw is made of a common 1 inch wood screw, inserted from the side on which the spool is glued, and the head countersunk, in the centre of the width of the carriage, and $\frac{1}{4}$ in. from the end, thus passing through the middle of the joint that was cut.

To prevent the screw from turning and also from dropping out, a small wire staple, similar to a double-pointed carpet tack, is driven across the head of the screw, so as to lie in the groove; and a nut is made from a piece of hard wood 1 in. long, $\frac{1}{2}$ in. wide and $\frac{3}{8}$ in. thick, cut to the shape of an oval and slightly rounded on the under side, so as to bind only on the bottom, as shown at A. In order to get a good, clean thread in the nut, a tap may be made by taking a common screw of the size you are using, and with a saw-file making three or four grooves lengthwise of the thread deepest at the point.

To reduce a drawing to one-half the original, set the instrument so that a hole at B, which is in line with the points of the pencils at C and G, is just as far from G as that point is from C. I always make the pencils fit tight in the spools by wrapping paper around them, but a screw may be inserted to hold them, but it is not necessary. In setting the instrument it is always necessary to have the pencils and the hole in which the fulcrum is placed, perfectly in line. For this purpose a piece of wood the size of an ordinary lead-pencil, about four inches long, with a knitting needle driven into the end, so as to be in line with its centre, is very useful, as by placing it in the carriage at C, and then sighting across the point of the pencil at G to the hole in B, they may be adjusted perfectly in line. The distance from B to C represents the original, from B to G the reduced copy; by varying either, any amount of reduction may be made.

Instead of two pencils a piece of hard wood the size of a pencil, sharpened to a point, may advantageously be used in C, when reducing and in G when enlarging.

At A, on the under side of the piece AB, and just beyond the block under the screw, is glued another block $2\frac{1}{8}$ in. long, of the form shown; and at its lower extremity is fastened by a screw, a small wheel, readily made out of a coat button, and projecting below the bottom of the block to which it is fastened, $\frac{1}{8}$th inch.

When passing from point to point of the original, and not wishing to make a mark on the copy, the pencil may be raised from the paper by raising the joint at F a sufficient amount.

Bust Modelling.

ADELAIDE F. SAMUELS.

NOW if you are fully satisfied with the profile, you can begin measuring for the front view. You have the height of the forehead already; you now want to find the distance across, from temple to temple, as shown in Fig. 5, then from the same point on the temple to the ear. Next measure from eye to eye, mark the clay to keep the measurement, then find the height of the nose, between the eyes, to the inside corners of the eyes, and work out the clay between the nose and the eyes, being careful not to disturb the profile. Next find the length of the eye, then the distance from the end of the eyes to the ears. Do not attempt to do any fine work about the eyes yet.

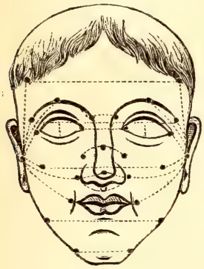


Fig. 5.

Now find the distance from the top of the eyebrow to the end of the nose, then from the top of the eyebrow to the ear, and work away the clay, of course, until you can get those measurements on it; and so on, until every measurement, as shown on Fig. 4 by the dots and dotted lines, has been taken and worked out: when you will have an image that will not be at all flattering to the sitter. It will resemble more a pagan's idol, but don't be discouraged: Rome was not built in a day, you know.

Now we must pay particular attention to each feature separately, beginning with the *Forehead.*

First be sure that you have not lost the profile, by comparing it well with the sitter's, then model the clay, very carefully, on both sides, with tool No. 1 until you have an exact copy of the sitter's forehead, as seen from every point; take extra measurements, if necessary, and if you should take off a little too much clay, you can add more by wetting a piece and rubbing it on with tool No. 2, so that it will not show. After you are quite sure the forehead is shaped as it should be, go over it with tool No. 2 several times, holding the tool firmly, and working it about in fine circles until the clay is as smooth as the sitter's skin.

The next to take all your attention will be the *Eyes.* Perhaps no part in bust-modelling is more difficult than getting the two eyes exactly alike, and also exactly like the sitter's. The great trouble with new beginners, is, they invariably model them *flat,* like a cat's eyes, when they should be more like Fig. 6. If you look well at the sitter's eyes you will see that the outside corners set back farther into the head than the corners near the nose; also the lower part is farther in than the top.

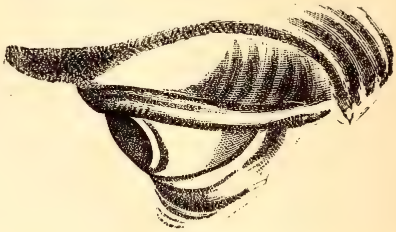

Fig. 6.

Some sculptors model the eyes plain, while others mark the colored part by sinking it in. As all the old masters made them plain, we can afford to.

Model the lids distinctly, perhaps a trifle thicker than the sitter's, for effect. Omit the lashes, of course, and the eyebrows, also, unless they are very thick and shaggy on the sitter, then they are to be added after the face is finished, in the same manner the hair is.

The next to claim attention is the *Nose.* You have only to model it as near the sitter's as possible. Take as many measurements as you like, do not lose the profile, and be sure before it is done, that there are no sharp corners or edges about the nostrils. All must be rounded and smoothed to perfection.

Next comes the *Mouth.* You will find it difficult to get the corners just right. You must look at the sitter's mouth from every point of view, and copy it in the clay, always being careful not to disturb the profile. After you have all the *curves* and *angles,* you can make the *color-line,* which is done, not by making a *distinct line,* but by working the clay, where the lips are red, one way with your tool, while all around it is worked another way.

The *Chin* and *Cheeks* must each be measured and copied, and nicely finished.

The *Ears* must be measured from the outside rims with the calipers, then one at a time must be modelled, measuring every way with the dividers as you go along. There is much satisfaction in modelling the ear, it can be made to resemble life so closely. You can use

your finger to advantage in smoothing it off, after you have got it the correct shape.

Next take all the measurements of the *Skull,* without regarding the hair, and work away the clay for them, so that your bust will appear "bald-headed all over." Take the measurements for the neck also, but you need not finish it off nicely until you are done with the next in order, which is the *Hair.*

Wet some of the pieces of clay and work them together until they form a mass that is *almost* thin enough to run through your fingers; take some of this in your hand, and throw it carelessly upon the skull, twirling and twisting it with the fingers until it takes the form of the sitter's hair; repeat the operation of adding, twirling and twisting the soft clay upon the bust until it has as fine a head of hair as the sitter has. Do only half the head at a time, that you may keep the parting clean, and be careful to have it come just as it should over the forehead. The *quicker* and *more carelessly* the hair is "thrown on," the better it will look, if it is done gracefully. It must not be touched again until the wet clay is as dry as the other, then with the small end of tool No. 4, go over it lightly, letting the tool always take the same course the hair takes.

Next come the *Neck* and *Shoulders,* which must be measured and modelled as near like the sitter's as possible, then nicely finished.

In order to make the *Drapery,* if the bust is to be draped, you must manufacture something that resembles a neck and shoulders, to throw the cloth over for a model. A piece of cloth, cut and sewed, so that it would fit over the sitter's shoulders and neck, then stuffed with straw or cotton, while a lath, nailed to a bench, as in Fig. 6 run up through the centre of it to keep it in position, would answer the purpose.

Throw the cloth you intend to copy, in graceful folds over that, and do not let the position get disturbed after you have it adjusted to suit you.

Some artists *dampen* the cloth before arranging it; they say it makes better folds when damp, and remains in place better; while others say the folds when damp, are not *natural.*

Do not try to *make* the folds in the cloth unless you want them to appear *stiff:* throw it carelessly over the shoulders, and let it take its own position; if you do not like it, throw it again and again, until you are suited.

Now take strips of clay as nearly the size of the folds as possible, and place them over the shoulders of your bust, until you have as many on it, and in the same position, as in the cloth model. After you have them all roughly reproduced, go over them with tool No. 1, and copy the cloth as closely as you can. Unless

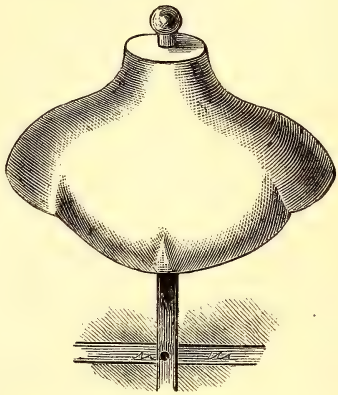

Fig. 7.

you are careful to note all the rises and depressions, and reproduce them in the clay, your drapery will not be a success.

After that you can spend as much time as you want to, doing "nice work," or putting on the finishing touches. Compare the face once again with that of the sitter, to see if the likeness cannot be improved, and when you are perfectly satisfied with it, if you *ever can be that,* you can make your preparations for *Casting the Bust in Plaster.*

To be continued.

Lessons in Magic. IV.

HOW shall we have the particular card drawn from the pack, which we wish to have, arise? That is what I promised, in my last article, to explain, and that promise I shall now try to fulfill.

The best way to do this is by all odds by *forcing,* but as that requires more practice than most amateur magicians care to devote to it, we shall describe another, but more clumsy method. This is by means of what is known as a *forcing pack.* It is a pack made up of six or seven kinds only, say eight of the ten of clubs, eight of the Jack of spades, eight of the three of hearts, eight, seven of diamonds, eight queen of spades, and eight deuce of diamonds. Of these cards all of a kind are gathered to

gether, and then are placed on top of each other, forming apparently an ordinary pack.

Armed with a pack of this kind, the magician goes into his audience, and approaching some lady or gentleman, begs that a card may be drawn. As the person puts out his hand to take the card, the performer runs off the first eight for him to select from, keeping the others in one solid mass. To the next person he runs out the second eight, and so on until six cards are selected. Of course in each instance all but the cards from which one is to be selected, are kept together in a solid mass, and there is no temptation to any person to draw one of them.

It is, as I have said, a very clumsy method of doing the trick, and not to be compared to legitimate *forcing*. Before I can explain this, it will be necessary to explain the first great principle of card manipulation, known as *making the pass.*

Making the pass consists in passing one or more cards from the bottom to the top of the pack, or *vice versa*. By this means the conjuror not only knows where certain cards are to be found, but has them completely under his control, and can, in a second, change the position of a card from the place in the pack where the audience have just seen it, to such place as may best suit him.

To perform this most important piece of legerdemain, hold the pack in the left hand, and spread it open with the right so that a card can be taken from it. The card having been drawn, separate the pack into two parts, and extending the part which is in the left hand, request the person who drew the card to place it on top of that packet; this being done, put the packet which is in the right hand upon the top of the left hand packet, letting the third finger of the left hand come between the two. This will make an opening between the packets, but being at the end which is towards the performer, and the other end appearing closed, the presence of the third finger will not be suspected.

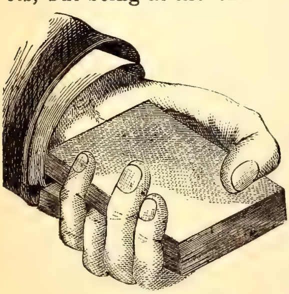

Fig. 3.

The pack is now in the position shown in this cut; next, with the thumb and the two middle fingers of the right hand, seize the two ends of the *lower packet* so that the pack is now held, as represented in Fig. 4.

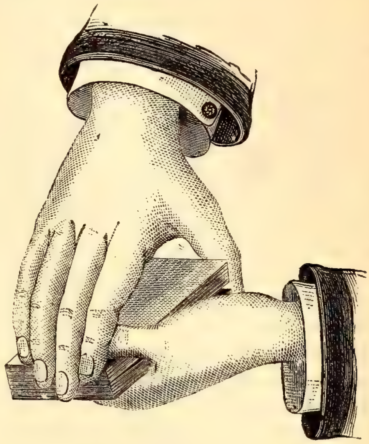

Fig. 4.

Everything is now in order to *make the pass,* which is done as follows: the right hand presses one side of the *lower packet* into the fork formed by the forefinger and thumb of the left hand, and holds it there, while the fingers of the left hand which hold the *upper packet* are drawn back as if to open the hand, the right hand being slightly arched to allow of this; the lower packet is then raised by the right hand, until the edges of the two packets meeting, form an angle as in Fig. 5.

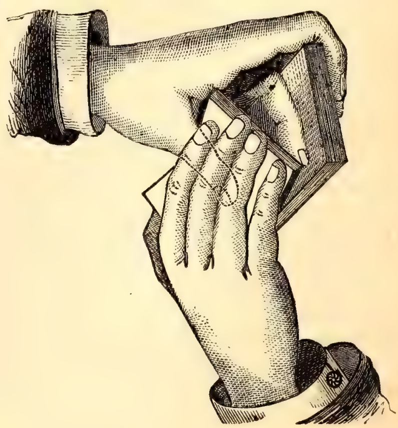

Fig. 5.

The fingers of the left hand are now closed, and the upper packet in this way laid on the palm, while the lower one is placed on top of it, the position of the two being thus reversed.

These movements must of course be practiced until they can be made with the rapidity of thought, but even when this proficiency is attained, it is not well to attempt *making the pass* immediately after the card is replaced in the pack, for at that moment the eyes of the spectators are fixed on the hands of the performer, and no matter how rapid his manipulations may be, there is always more or less of a shock or tremor caused by the cards pressing against one another, and this being noticed, may give rise to a suspicion that by some means or another the card has been changed. It is better, rather, to wait until their attention has been called off, and then *make the pass.*

Having become dexterous in making the pass, you may now attempt *forcing.*

The card to be forced, being, we will suppose, either on the top or at the bottom of the pack, *make the pass,* and so bring it to the centre. Place that which is now the upper pack,

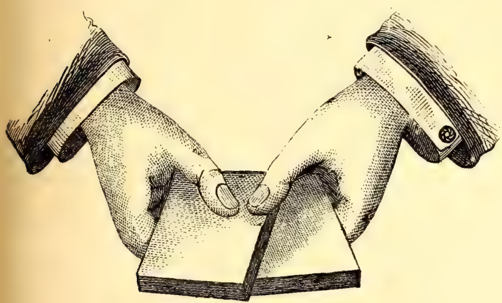

Fig. 6.

on the lower one, in a diagonal manner, as in the illustration, so that the two packs look something like a fan when half way opened.

Suppose that the pack is in the right hand, the top packet will be under the control of the left hand.

Spread out the cards of this packet with the fingers of the left hand, and the thumb of the right, always remembering to keep in sight the card, to be forced; if this card was on top of the pack before *the pass* was made, it will now be the first one of the lower packet, and if the under one of the pack, will be at the bottom of the upper packet.

Present the pack to some person, with the request that he or she, (and I must here remark that it is much easier to force a card on a lady than on a gentleman) will draw a card, "which ever one you like." At the moment that his hand reaches the pack, quietly slide along the cards of the top packet, by means of the right thumb, until just as he is about to draw, when you must so manage that *the card* will be invitingly before him. By thus sliding along the cards, you at once do away with the idea that there is any preparation about the matter, at the same time that you are, by this means, enabled to reach the card you want to force and which in ninety-nine times out of a hundred, will be drawn.

It requires some little practice, but as it is almost indispensable in magic, the time spent in perfecting yourself in manipulation will not be lost.

The Heavens for February.

DOUBLE STARS.

Under this head we will give each month some tests for telescopes of different grade.

a Ursæ Minoris (Polaris) is a fine double. The companion is faint and difficult to "pick up" with a small telescope. An aperture of two inches and a power of sixty will separate them. The companion is estimated to be of the $9\frac{1}{2}$ mag. and $18''.6$ distant from Polaris, having a pale white tint. Rev. W. R. Dawes saw it with his large refractor, having its object glass diminished to one inch and using a power of eighty, but no small instrument having an object glass less than two inches will show it. After once finding it with a large glass it is much easier to catch it in small ones. A power of thirty-five or forty will show about thirty stars in the field with Polaris. Proctor mentions this as a good test for the illuminating power of telescopes.

METEORIC SHOWERS.

Some years ago a committee was appointed by the British Association for the Advancement of Science, to systemize and analyze all the facts and reports concerning luminous meteors. The epochs which this committee established we will give each month. For Feb. they are: 10th, 15th, 18th, March 6th and 12th. These are simply the dates on which star-showers have occurred with more or less frequency, and for those interested in meteoric astronomy a fine field for investigation is presented to establish their periods and radiant points.

These two lines that look so solemn
Were put in here to fill this column.

THE

YOUNG SCIENTIST.

Published Monthly at 50 cents per year.

Postage free to all parts of the United States and Canada, except New York City. Our absurd postal laws make the charge for delivering our journal to subscribers in New York city five times as great as that required for transporting it across the continent, and delivering it to subscribers in San Francisco or New Orleans. We are therefore compelled to charge our New York subscribers the 12 cents postage which we have to pay on city addresses.

Care of the Microscope.

THERE is scarcely any instrument that is more easily injured by rough usage than the microscope, and there is none that is more durable, provided proper care be taken of it; and as microscopes are as frequently injured from want of knowledge as from want of attention, a few hints may not be out of place.

The great enemy of the microscopist, both in regard to the preparations on which he spends so much labor and the instrument which he uses for examining them, is dust. To the microscope itself, dust is utterly destructive. It not only dims the glasses and makes specks on them which appear to be part of the object, and thus cause errors, but it gets into the working parts, grinds them and wears them out rapidly, destroys the accuracy and evenness with which they move, and clogs them so that great force is needed where force should not be applied. Often and often we have seen microscopes sent to the maker for *repairs*, which only needed *cleaning*.

The first thing then is to exclude dust. The microscope should never be exposed except when it is in use, and then it should be kept from all extra invasions of dust. When not in use it should be kept in its case, and as the taking out and putting back of the instrument is always more or less of a bother, the case should be made to receive it without any necessity for its being unscrewed or taken apart except in the case of travelling microscopes or seaside microscopes, where great compactness and portability are desired. Hence the upright case should always be chosen, and it should be large enough to take in the microscope with its eye-piece attached. If it gives much trouble to take the microscope out of its case, the instrument will often lie unused when great advantage might be derived from employing it, and this not on account of the laziness of the owner, but simply because he has not time. When it takes ten minutes to get the microscope ready and five minutes to examine the object, the examination will not be made if we have only ten minutes at our disposal.

The case, of whatever shape, should close tightly, and if kept in a region where the dust is plentiful and of a very grinding character, a thick covering of some close material, like oil-cloth or leather, should be thrown over it. It should be so loose that it shall be but a moment's work to take it off or put it on, and it is best made in the form of a case or bag, the edges of which are firmly sewed together. Ordinary porous cloth allows dust to pass, and will not answer.

When, in spite of all precautions, the microscope has been soiled, it should be carefully cleaned, and for this we will give directions in our next issue.

Examination of Powders.—A New Employment for the Microscope.

The value of many materials that are used in the arts depends very much upon the degree of fineness to which they are reduced to powder. This is usually judged by the sense of feeling—a little of the powder being rubbed between the fingers. In some cases the appearance of the powder as to color and its behavior when laid in a little heap, and moved about with a knife or spatula, is a good guide. Most substances, when reduced to very fine powder, behave like fluids in some respects and like solids in others. For example, they can be made into a heap with a perpendicular face, which cannot be done with sand for example. (Try this with flour or with silica—sand very finely powdered). But the most accurate way of judging of the fineness of powders is by the microscope. Under a power of 100 diameters, most powders look coarse; 250 shows well some powders which

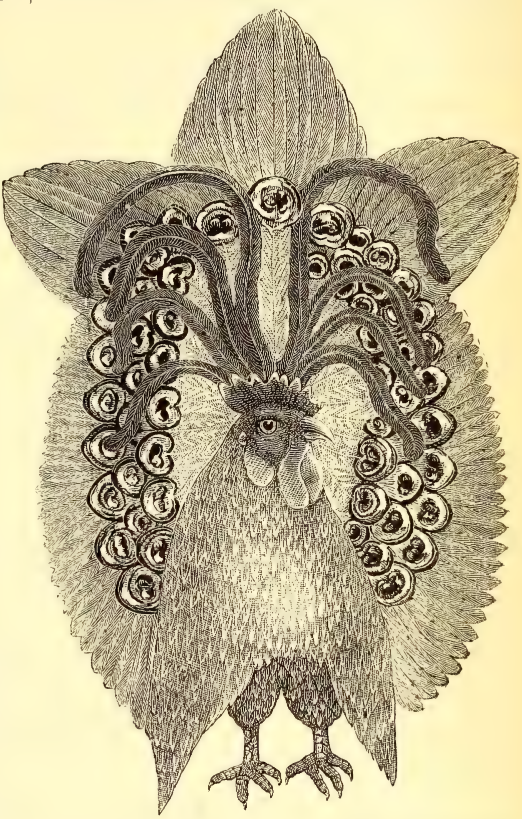
are regarded as very fine, while there are no powders in market which do not appear coarse under a power of 500 or 600. The methods of examination will probably vary under different circumstances, but in any case, the operation is a very simple one.

In this case a doubling of the magnifying power more than doubles the efficiency of the microscope, for this is one of the few cases where areas and even cubical contents are of account. A fragment seen under a power of 100, will appear as large as a fragment that is not only 10,000 times, but 1,000,000 times as large, and under a power of 600 diameters, a fragment weighing the 1-10,000th part of a grain would appear as large as one which weighed over three pounds avoirdupois! This seems very astonishing, but a little calculation will readily show its accuracy and points very strongly to a hitherto neglected but very important employment for the microscope.

Fire Screen, Lambrequin Ornaments, etc., of Cock's Head and Plumage.

Boys, and girls too, should learn the easy, and interesting art of Taxidermy, by which they may not only preserve and mount the various pets they are so unfortunate as to lose, but may also with very ordinary fowls, birds and animals of various kinds, make elegant household ornaments and embellishments; perhaps establish a cabinet-case, in which, on a tree they will have various birds, while on a rock a fawn will stand as naturally as if in its forest home; and rabbits, squirrels, "'coons," etc., peep out from different coverts, or lie upon the grass; stoop to drink from a tiny lake, or reach up to the foliage of the tree above them; while the faithful dog you loved so well, appears to guard the mimic forest, and the several pussies you have lost, look as natural as in life, upon the roof of the cottage, arranged in the corner. This is by no means an impossible attempt, and we could describe three such pretty museums, one of which is arranged in the recess of a sitting-room, and is a source of constant delight. It is inclosed with glass doors, and is a pretty bit of nature. But a very simple first lesson is the one I am about to describe to you now, as a means of making a pretty ornament. I will suppose you have a handsome specimen of a chanticleer in the yard which you will kill in a humane way, by cutting a blood vessel in the neck, which is easier than wringing or chopping it, and will not spoil the beautiful feathers; now when dead, place it on its back on a piece of clean board, and having provided yourself with a sharp pen-knife, a pair of cutting plyers, a pair of strong scissors, of medium size, a button-hook, a salt spoon, and a hand vise, a needle and some linen thread, (a hone on which to touch your knife occasionally); annealed wire (you can make it red hot, and leave it in the air until cold, which will anneal it very well); some hemp, raw cotton (wadding), whitening, pulverized alum or chloride of lime and arsenic or arsenical soap, a brad-awl or two, some pieces of old soft rag, and a wet towel on which to wipe the fingers.

Spring is the best time for preparing wild birds, but our cock may be taken when convenient. Keep



the bird for three days—if the weather will permit, as the skin will then separate easily.

Lay the bird on its back, part the feathers along the breast where an open seam appears, extending round the lower part of the neck; cut around this and separate the body from the neck, carefully, then turn the skin over the head; the back of the skull will now appear, cut a small hole in this in semi-circular form, turning it up like a trap door, and into it pass the little spoon, scooping out all the brains, etc., then with a small half ounce syringe, squirt water gently in and wash out the cavity, into which dust the alum and arsenic mixed, and fill with wadding.

The next step requires care—namely, the eyes; cut carefully round with the sharp knife, pressing the orbit gently to aid in crushing the small bones, separating the ball from the roof of the mouth, then catching the ball with small forceps, you can draw it

out from the socket, wash, and dust with the alum mixture, then fill with cotton.

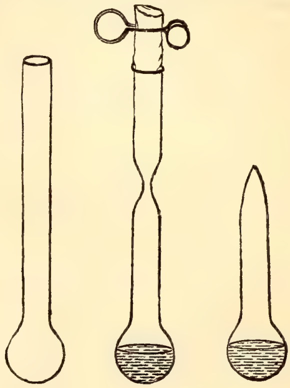
Next, wash the neck carefully, and cover with the powder; then make a frame of wire which must consist of a large circle—of size of the large end of the neck, and a very small one fitting in the narrow part next the head, uniting them with four straight pieces, that will keep the neck extended; then cover with muslin wound round each wire, and putting the frame in the open skin, fill the whole cavity with tow or cotton. Next put in the eyes, consisting of beads or, far prettier, the regular glass eyes sold by taxidermists and fancy stock dealers. If not too large, these are easily inserted after removing the ball of cotton, and the juices from the lid will form a cement that will hold them. Thus mounted, your head will dry out without any trouble, but if the weather is warm, use corrosive sublimate, instead of alum and arsenic.

Next cut a piece of pasteboard fifteen inches long (more or less), which cover neatly with colored muslin. Around the edge sew a border of handsome peacock's or cock-tail feathers, and a row of each is very beautiful, then place the cock's head in place, and in the centre of the back arrange several graceful waving plumes. By lifting the outer row of feathers, the stitches are easily inserted.

Wash the feet very clean, rub the raw end with the alum and arsenic, score the under part of each claw and rub in all the arsenic and alum possible, then sew up the skin; varnish (when quite dry) with dammar, and fasten as shown in the illustration.

The Water Hammer.

This is a very curious little piece of apparatus, which any boy can easily make for himself. Take a piece of glass tubing with pretty thick sides; the bore should be about one-fourth of an inch, and the outside diameter about three-eighths of an inch. Heat the end strongly in a spirit lamp or Bunsen burner. The latter will answer without a blow-pipe and even a good spirit lamp with an organd or circular wick will answer. The end of the tube being soft, draw it away, and the glass will gradually close. It must now be thickened by heating it strongly in the flame, rotating it constantly, and pressing the glass carefully up with a piece of metal. When the glass is thick enough, bring it to a bright cherry red, remove it from the flame and blow into it, rotating it all the while. It will soon look like A. Now heat it about six inches from the ball, and draw it out as shown in B, until the bore is not larger than a pin. Cool it very gradually, and when quite cold fill it two-thirds full of water. If you have some rubber tubing and a spring clip as shown at B, they are the most convenient for the next step. But a good sound cork will answer. Or if you have the rubber tube and no clip, put on the rubber, and in it put a piece of glass or metal rod about one-sixteenth of an inch less in diameter than the bore of the tube. Now grasp the tube, just below the rubber tube, with a common wooden spring clothespin, and hold it over a small spirit lamp until one-third of the water has boiled away in steam—passing out between the rubber tubing and the glass or metal rod. Let an assistant now tie a fine but strong cord firmly around the rubber tube, and it will be pressed against the inner rod so that it will be closed air tight, and remember that at the very instant that the cord is drawn tight, the lamp must be removed or more steam will be made, and you may have a boiler explosion on a small scale. By applying a sharp jet of flame to the



The Water Hammer.

thin part of the tube it may now be sealed up air tight, or *hermetically* as it is called, and the water hammer is finished, looking like C, but not quite so dumpy.

If you have done everything properly, the tube and ball will now be empty of every thing except a little watery vapor—all the air having been driven out by the steam from the boiling water. If the bulb is shaken, the water meets with no resistance in its movements and makes no froth or bubbles. But the strange point is that when the water is thrown quickly from one end to the other, it strikes the glass like a hammer, and gives a sharp metallic ring. Hence the name. Under ordinary circumstances, when water is driven against a hard body, the air forms a cushion, and a slushing sound is heard. Here however, the cushion is absent, and the water comes at once in contact with the glass, in which it produces the same vibrations that a solid body would make. These vibrations pass from the glass to the air outside, and thence to our ears.

A Seasonable Experiment.

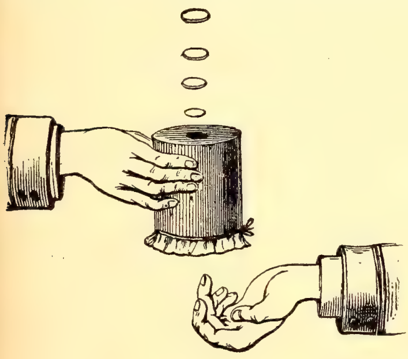
It has been found that the temperature at which water freezes depends upon the pressure to which it is subjected, and a block of ordinary ice, if subjected to sufficient pressure, might be entirely melted. The following very striking experiment which illus-

trates this fact, requires no special apparatus and is easily performed. Lay a block of ice across the back of two chairs, and over it pass a piece of fine iron wire the ends of which have been twisted together. From the wire suspend as great a weight as the wire and chairs will support, say 50 to 100 lbs. It is evident that since the extent of ice surface on which a fine wire will press is small, the pressure *per square inch* on the ice must be very great. The consequence is that just beneath the wire the ice is melted, and the wire drops down a little. As soon as the wire falls however, the water above it is relieved from pressure and immediately freezes. In a short time therefore, the wire passes completely through the ice, and allows the weight to fall, while the ice is not broken, nor is any mark visible where the wire has passed through.

Smoke Rings.

One of the most beautiful, though perhaps not one of the most brilliant experiments in chemistry, is the formation of smoke rings by phosphoretted hydrogen. In a still room, dimly lighted and with a small audience, the bright, but short-lived flashes of light and the self luminous rings of smoke, gradually widening as they ascend, and forming a series, nearly extending to the ceiling, are beautiful beyond description.

Unfortunately however, phosphorus is not a very safe article to handle, and unless in careful and skilful hands, the preparation of phosphoretted hydrogen is apt to give rise to ugly accidents. The following experiment is without danger, and is very interesting and beautiful: Take an ordinary can, such as is used for tomatoes, etc., and in the bottom punch a clean hole, about one-third of an inch in diameter; over the open end stretch a sheet of paper. This is best done by wetting some rough manilla or drawing paper, stretching it over the mouth of the can, and tying it down as in the figure. When dry, it will be perfectly smooth and tight like a drum. Throw a little smouldering brown paper into the can and it will soon fill it with smoke. If after a few seconds the can be held in one hand, and tapped with the other, very perfect rings will issue with a speed proportionate to the strength of the tap. These smoke rings deserve careful study, and we will return to them again.



Smoke Rings.

Varnish for Paintings.—" A good varnish can be made as follows: Mastic, six ounces; pure turpentine, one half ounce; camphor, two drachms; spirits of turpentine, nineteen ounces; add first the camphor to the turpentine. The mixture is made in a water-bath, and when the solution is effected, add the mastic and the spirits of turpentine near the end of the operation, then filter through a cotton cloth. The varnish should be laid on very carefully.

Steel Rust.—According to the *Chemiker Zeitung*, articles of steel which have become rusty may be cleansed by brushing with a paste made up of thirty parts cyanide of potassium, thirty parts curd soap, sixty parts of precipitated chalk, and a sufficiency of water. Great care is required in preparing and using this poisonous mixture.

The Camphor Barometer.—This toy, for it is little else, has been extensively sold as a reliable weather indicator. It was carefully examined years ago, however, and its indications were not found to be of any value. The reason of this is that the cloud which constitutes the "indicator" is formed either by pressure or by heat. Moreover the ingredients are apt to change with time and exposure, and this forms another element of uncertainty. The recipe as generally given is as follows: Dissolve two parts of gum camphor, one part of saltpetre, and one of sal ammoniac in 100 parts of 95 per cent alcohol, and add enough distilled water to precipitate a small portion of the camphor. Place this in a large glass tube with the upper end drawn out, so as to leave an opening not larger than a pin hole, or the end o the tube may be closed with a good sound cork. The instrument is to be fixed in the open air, out of direct sunlight.

Benzine and Benzol.—These two names are often confounded with each other. The first is usually applied to the product from petroleum, and the second to that from coal tar. They differ considerably in their properties, and as benzol is extensively used in microscopy, etc., disappointment has frequently been occasioned to those who have used benzine instead. Hager remarks that petroleum benzine, on dissolving iodine, assumes a *raspberry red* color, while coal-tar benzine becomes *violet*. Asphaltum is soluble in coal-tar benzine and insoluble in petroleum benzine.

Exchanges.

Yearly subscribers to the YOUNG SCIENTIST have the privilege of inserting three exchanges (or one exchange three times) during the year. This privilege is strictly confined to *exchanges; buying and selling* must be carried on in the advertising columns, where the charge is 30 cents per line. Each exchange is limited to thirty words, making about four lines, and in order to receive attention must be written on a slip of paper by itself. We file all letters received and have no time for copying out exchanges and queries.

As we desire to make the journal of the utmost value to *all* and not merely to serve the interests of individuals, we shall strictly adhere to these rules, which are certainly liberal, giving as they do advertising to the value of $3.60 free to each subscriber.

A combination scroll saw and lathe, cost $16.00, to exchange for a printing press or type. C. H. Parker, Coldbrook Springs, Worcester Co., Mass.

A bill boka board, in perfect condition, cues and balls, cost $8 very recently, in exchange for a scroll saw in good condition. S. F. Allen, 47 W. 12th st., city.

Scientific American, 1870 to 1878, over 450 Nos., not bound, to exchange for good Natural History, opera glass, watch, gun, or offers. J. T. Bell, Franklin, Pa.

Groff's Model Suburban Architecture wanted in exchange for Nicoll's Railway Building, Templeton's Practical Examination of Steam and Steam Engine, and Colburn's Locomotive Engine. All entirely new. F. H. Jackson, Angelica, N. Y.

Wanted, a small turning lathe, state what is wanted in exchange. Ralph A. Pillsbury, P. O. box 555, Belfast, Me.

To exchange, beautiful rose, milk, greasy and smoky quartz, graphic granite, orthoclase, etc., for aboriginal relics, coins, or other minerals. Prof. C. L. R. Wheeler, Bedford, N. Y.

A collection of invertebrate fossils, accurately labeled and worth $225, to exchange for good microscope. The instrument must be of modern make, and in first-class condition. S. Calvin, Iowa City, Iowa.

A collection of foreign and dept. stamps, or a large collection of bird eggs of the Southern States, for a set of drawing instruments or books on plain and ornamental penmanship. Address Q. R. S., Mt. Pleasant, Washington, D. C.

Wanted almost anything in exchange for a complete set of cabinet maker's tools. The chest alone is worth twenty-five dollars. Address Mr. Clark, P. O. box 37, Brooklyn, N. Y.

For exchange, two good dial telegraph instruments, and two good Morse telegraph instruments, for printing press or bracket saw. James Scott, 20 Patchen ave, Brooklyn.

A card printer, type and cards worth $1.50, and the book "His own Master" will exchange separately or all together, books, or offers. Geo. R. Simpson, Janesville, Iowa.

A stationary cylinder steam engine, or hardware goods in exchange for an electric call bell. L. J. Otis, 973 Prairie Ave., Chicago, Ill.

Wanted for a good Gundlach No. 4 (¼) Objective, a 1½ or 2 inch Objective of wide angle. C. Onderdonk, Brooksburg box, Madison, Ind.

A spy glass costing five dollars, to exchange for a companion scroll saw and turning lathe in good condition. John Buck, Brazil, Clay Co. Ind.

Forty good photo-lantern slides, plain and colored, for a good printing press and outfit; or a small screw cutting lathe; or first class microscopic objectives, or offers. Wm. R. Brooks, Phelps, N. Y.

Wanted, a small rifle, in good order, bore 22-100, for a telegraphic key and sounder, instruments are made of brass finely wrought, mounted on a japaned iron base. Louis E. P. Smith, 6 Alpine st, Boston, Mass.

Ferns, mounted or unmounted, for Northern species of same. List of those on hand and those wanted sent on application. Maj. R. H. Wildberger, Ky. Mil. Inst., Farmdale, Ky.

Two good business lots, central, in Ellsworth, Kan, for good microscope, accessories and books, chemical balance, or gold watch. Wm. Zimmerman, 114 Dearborn st, Chicago, Ill.

To exchange, a collection of 500 rare stamps, with book which cost $1.50. The whole worth about $7.00. State offers. Albert N. Webster, 106 South Park ave, Chicago, Ill.

Hinkley knitting machine, worth $40, for a watch or breach loading shot gun, Harry Holden, Black Earth, Dane Co. Wisconsin.

One dozen (assorted) mounted objects for microscope, cost $2.50 (By J. W. Queen & Co.) for useful books on any subjects, or old U. S. coins. W. M. Stribling, P. O. box 350, Circleville, Pickaway Co, Ohio.

Cabinet mineral specimens, for Masonic publications, or other instructive books. Light reading not wanted. J. P. Clough, Junction P. O., Lemhi Co. Idaho.

Swiss watch lathe, brass, steel shaft and box, cost $25. Also a gear cutting lathe nearly complete. Exchange for minerals, microscopic slides and books. H. A. Cutting, Lunenburg, Vt.

Twelve dollars worth of parlor tricks, very best make, in exchange for a good microscope or a scroll saw with lathe attachment, of equal value. Prof. C. H. Houghton, Middleboro, Mass.

Book on magic, cost $2.50, for back numbers Young Scientist, and foreign stamps. Omega, Post Warrensburg, Mo.

Wanted, Parrishes Pharmacy and chemicals. State what is wanted in exchange. C. O. K., 1520 Fairmount Ave, Phila.

Stereoscopic views of New York city and vicinity, in exchange for fossils from the Western states and territories. T. P. Wendover, P. O. box 1862. N. Y. city.

Chemical apparatus or balance, spy glass or saw wanted, in exchange for novelty printing press, with sixty fonts of type. Alex, 151 East 33d st, N. Y.

Microscope worth $7.00, and cabinet with forty good slides; for better instruction or other educational apparatus. Particulars on application. Arthur Hobart, Penn Yan, N. Y.

Wanted a copy of Bourne's Treatise on the Steam Engine, for a full set (7 vols. bound) of Technologist, cost $19.25. W. J. Allen, 256 Twenty-second st, Bkyn.

Wanted, a three wheel "velocipede" large size, state what is wanted in exchange. Peter J. Murray, box 743 Wilkesbarre, Pa.

To exchange, one Bunsen and two Smee batteries; for books on electro-metallurgy or quantative or qualitative analysis. A. W. Palmer, care of Watch Co. Springfield, Ill.

A pistol in good order, cost $3.00, in exchange for an electric bell. A. W. Honywill, 217 Cabot st, Boston, Mass.

Collection of over 500 rare stamps, including Ecuador Cape of Good Hope, Barbadoes, Honduras, etc., in exchange for microscope, minerals, or scientific publications. Jas. G. Kitchell, 345 Race st, Cincinnati.

Music box, printing press, cost $35, and complete outfit for cutting stencil plate for marking clothing, cost $25, for boiler large enough for ¼ horse power. Geo A. Battles, Westminster, Mass.

Three-quarter portrait camera tube, with box and tablets all new; for books on science, medicine, history, or travel, or microscopic slides. J. S. Mason, Medina, Ohio.

Wanted, a printing press or set of draughting instruments for a C cornet (worth $30.00) or Queen's Universal Household Microscope and accessories. G. E. T., Box 475, Westboro, Mass.

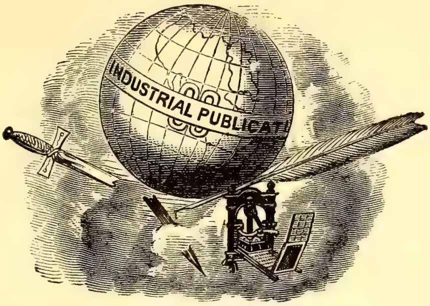
BIRD HOMES.

The Young Scientist

SCIENCE IS KNOWLEDGE.



KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, MARCH, 1879. No. 3.

Bird Homes.

BY A. W. ROBERTS.

BLUE BIRDS, martens, wrens, and the European sparrow, will all occupy houses built for them, seeming to prefer to be near our homes and to court our protection.

When traveling along our eastern coast line, from New York to Maine, I found the European sparrow everywhere, even at Grand Menan; and I was much amused at the many crude and comical styles of bird houses in use. Milk cans, butter firkins, old straw hats and discarded beehives were utilized for this purpose, and in one case a farmer had scooped out several hook-necked squash and club gourds which he had fastened under the eaves of his barn, for some wrens, who had taken possession of them.

I found the prevailing school of bird house architecture to be of this style (Fig. 4)—very primitive and very ugly. And as if to add to their ugliness, they were often painted of either a dead white, ultramarine blue, bright green or yellow, and occasionally bright red, and even black.

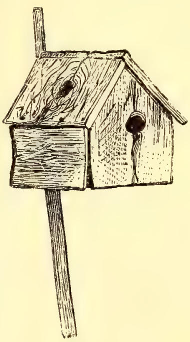


Fig. 4.

None of our native birds would be guilty of ever taking up quarters in a vermilion colored house, but those feathered tramps and loafers, the sparrows, ever ready to crawl into any hole or place to secure a footing, in this instance seemed color blind or indifferent so long as they obtained a roof to shelter them.

In painting bird houses, never use bright or glaring colors or gilding, as it is not only in bad taste, and not in harmony with nature, but to birds of modest and retiring habits is very displeasing. Imagine a pair of our plaintive-voiced blue birds dwelling in a bright yellow house! think of their rich blue against a vulgar yellow! Could any combination of colors be more inharmonious and displeasing to an educated eye?

All that birds require is a quiet and secure situation for their homes. My father some years ago fastened a number of flower pots against the side of a brick house. The holes at the bottom of the pots were made large enough for wrens, and too small for blue birds. As a battle had been raging for a number of days between the wrens and a pair of blue birds over the possession of the only bird house on the grounds, the flower pots pleased the wrens, who took immediate possession, and ceased their warfare on their neighbors.

I have since used flower pots extensively in constructing bird houses, and will try to give the readers of the YOUNG SCIENTIST my experience as a bird house builder.

Fig. 1 shows a seven-inch pot fastened against a stone wall; a hole is cut out of the bottom of the pot large enough to admit of either wrens or sparrows. For cutting the hole I use the large blade of a jack-knife, well notched, and soften the ware thoroughly with water. This reduces friction, and prevents clogging, or drawing the temper of the blade. The hole, after it is cut, can be filed to any desired shape. The pot is held against the wall where it is to be fastened by leaning a post or board against it.

For a cement for fastening, plaster of paris is to be preferred to Portland cement for light work, and also for its quick setting qualities, which may be hastened by adding a little salt. The plaster should be applied rapidly about the rim of the pot, and against the wall, till a perfect union is formed. The pot and the wall must be first dampened with water, or the plaster will not adhere.

After the plaster has set, the board prop is withdrawn, and work on another pot begun. When all the pots are fastened in position, the plaster is given twenty-four hours to dry and harden before putting on the rough coating, as the weight of this coating might break away the pots. The rough coating is applied as shown in Fig. 3, with a broad bladed table knife, or "pointing" trowel. I load the trowel with plaster; with the left hand I urge the flow of the plaster from the point of the trowel with a stick, the point of which has been well greased or soaked in oil, to prevent the plaster adhering and forming a knob.

When it is desired to make the bird houses look more picturesque, pieces of lichens and wood mosses may be fastened on with plaster; small branches of the vine may also be brought down and around the pot, and for a perch or rest in front of the entrance, a dead twig or branch may be used. These are also fastened to the pot with plaster.

After the plaster is perfectly dry, it should get a heavy coat of boiled linseed oil, mixed with a dull green, brown, or neutral tint. The oil protects the plaster from the action of rain and the atmosphere.

Fig. 2 is a hanging bird house. It consists of a nine-inch flower pot and an old milk pan. A hole is made in the bottom of the pot and pan large enough for a turned picket or stick to pass through, and to allow for the fastening of the straw which is to form the thatched roof. A hole is bored through the picket into which a cross pin of wood or iron is inserted, on which the bottom of the pan rests, otherwise it and the pot would slip off.

The milk pan is punched full of holes to allow the plaster to pass through and clinch, as it will not adhere to the smooth surface of the tin. In applying the plaster to the pot, I use an extra quantity on the inner bottom of the pan, to more firmly unite the pot and pan together. After the plaster has hardened, the rough coating is applied as before described. The pan, after it is filled with earth, is planted with tradescantia, German ivy, or Madeira vines, which will cling and twine to the brush cat screen. I have also used some of the more hardy of the succulent plants, such as house leeks, creeping charley, and semper vivum metallica, etc

The cat screen is made of the branches of black alder firmly bound to the picket, some two feet below the bottom of the pan, against which they press and radiate out, forming an effectual obstruction to cats, as well as looking very ornamental when the vines are growing among the mass of branches, buds and burrs.

The best and most ornamental woods

for making these screens are red birch (with the cones on), spruce with its rich buds, and sweet gum tree (liquid amber). These are all very pliable, and easy to handle. In making the thatched roof, the straw is first bound to the top of the picket with wire; it is then brought down to the top, extending over so as to form a continuous eave. The dishing of the thatch roof is controlled by the wire or twine stitching, which holds the straw together.

Fig. 3 consists of two 14-inch pots joined together at their rims *very firmly* with plaster. The lower pot is fastened to a large sized milk pan, and through the milk pan and pots passes a stout pole extending well out of the upper pot, on which is fastened the double thatched roof. The third roof of thatching is bound on with wire just below the rim of the lower pot, around which is formed a shoulder of plaster, otherwise the wire binding would slip off. This bird house can be divided into as many compartments as desired.

Where a number of pots and pans are to be fastened together, great care must be taken to firmly unite the parts together with a bountiful quantity of plaster, laid on thick. Much taste and skill can be displayed in the different designs formed on the pots with the plaster, but care must be taken to have them in good taste and in keeping with the surroundings.

Lessons in Magic—V.

I WILL suppose that you, my reader, are to give an exhibition of conjuring, and let me here suggest that when you do appear either in public or in private, that you use the plain, old-fashioned word "Conjuring," in preference to those high-sounding affectations, "Prestidigitation," and "Thaumaturgy." Well, your programme is prepared; your stage and apparatus arranged; the bell tinkles, the curtain rises, and you walk to the footlights and make your bow. Of course you are expected to make an introductory speech, and you do it in a few words, and then begin your performance with—well, I will suppose with

The Egg Ching-Ching.—This title has really very little reference to the trick, but then a title is absolutely necessary, and as this conveys no idea of what you are about to exhibit, it is as good as any other.

For the trick you use an egg, a glass goblet and two handkerchiefs, one large cotton one, and the other a small one about eleven inches square, made of red silk.

The goblet you place in the hands of one of your audience, and then select an egg from a number in a dish; the cotton handkerchief is spread over the left hand, and on it is laid the egg. You now approach the person who holds the goblet, and, asking him to hold it above his head, you cover it with the handkerchief, and at the same moment drop the egg gently into the glass.

"You all heard the egg drop into the glass," you say; "Now, Sir,"—addressing the gentleman who holds the goblet—"be good enough to shake the glass, very carefully, however, so as not to crack the egg, and tell the audience whether you think the egg is still there."

"You think it is? Very well. Now, ladies and gentlemen, watch me carefully, and you may detect the little piece of sleight-of-hand which I am about to attempt."

You proceed to turn up your coat cuffs, that all may see you conceal nothing there, and taking the small red silk handkerchief by one corner, with your right hand, say, "I use a red handkerchief for this trick purposely, as it contrasts very decidedly with my shirt cuffs, and should I attempt to conceal it in my sleeve, you would detect me. Now, if you will watch sharply, you will see it gradually disappear."

Place your hands together, with the handkerchief hanging from between them; move the hands slowly up and down, and, to the surprise of all, the handkerchief will be seen to gradually creep into your hands, until at last it entirely disappears. You open your hands, and there is—not the handkerchief—but the egg. This you place in an egg cup on your table, and then running to the person who holds the

goblet, you pull off the handkerchief which covers it, and there inside is the red handkerchief snugly stowed.

"Examine those carefully," you say, "and I will show you something more of the wonderful qualities of the egg."

But before going further, I will give the explanation of "The Egg Ching-Ching." As real eggs are apt to get broken, get a turner to make you a lot of wooden ones, which you have painted, some of a bluish white, and others of a light cream color, so as to look as near like the genuine article as possible. Into one of these drive a small staple, which you may easily make by cutting the head off a pin, and then bending it back till both ends meet. To this staple you fasten one end of a piece of thread, and the other end to the centre of the cotton handkerchief. Next you get *two* pieces of red silk—the kind known as Florence or Marceline is best, as it is flimsy and soft—and, finally, get a tinsmith to make a tin egg, with a hole in one side to admit of one of the pieces of silk being placed inside; this egg you have painted the same color as the wooden egg which has the staple in it. Your apparatus is now complete. Before commencing the trick, fold one of the pieces of silk into as small a package as possible, and place it in the cotton handkerchief, putting the tin egg under your waistcoat.

Approaching the audience, you keep the centre of the cotton handkerchief in your left hand, holding it in such a way as to conceal the piece of silk and the wooden egg.

Now call for some eggs, and when one is selected by the audience, take it in your right hand, throw the cotton handkerchief over it, and whilst it is covered, conceal the egg, either by dropping it in your sleeve or tucking it into your waistcoat. Withdraw the right hand, and tell the audience that the egg is under the handkerchief; they will probably doubt you, but to convince them that it is so, you pull up one end of the handkerchief and show the wooden egg, which will satisfy them. Now request some one to hold a goblet; throw the cotton handkerchief (which you still hold by the centre, to prevent the piece of silk from dropping) over it, and place the wooden egg and the piece of silk in the goblet.

Ask the person who holds the glass to shake it, so that all may hear that the egg is really inside. Being convinced that it is there, you produce piece of silk No. 2, which you allow the audience to examine, and then return to the stage. As you go on to the stage, you take the tin egg from under the waistcoat, and hold it concealed in your right hand. Take the piece of silk between your two hands, and begin waving them about, and at the same time manage, by means of your thumbs, to tuck the silk into the egg. When it is entirely in, close the right hand over the egg, and, going to the glass, lift up the handkerchief, being careful at the same time to take the wooden egg out. The audience, seeing *a* piece of silk in the glass, will suppose it is the same you held a moment before; and as you open your hand and show an egg in it, they will take it for granted that it is the one that was in the goblet.

As some inquisitive person may want to examine the egg, you may change it for a real one in this way. Have a little pocket cut in each side of the skirts of your coat, at just about the spot that your wrist would reach if your arm was dropped to its full length.

As you conclude your trick, approach some person on your left side, holding the tin egg in your right hand. Ask the gentleman if he will be kind enough to look at the egg and see that it is perfectly good. As he extends his hand to take it, you pretend to put it in your left hand, but retaining or *palming* it with the right, let that hand drop to your side, and slip the egg into the pocket in your skirt. The left hand, which is closed and supposed to hold the egg, you put out, to meet that of the person who is to receive the egg, and at the moment your hands meet, you open your left, and all are astonished to see that it is empty.

"Would you like to know where it is?" you ask. "See here." Open your waistcoat at the place where you hid the egg which was chosen first for the trick, and show it.

Engraving on Wood—II.

BY SARAH E. FULLER.

IN our last paper we told you how to make a drawing on wood, and we will now give some instructions in the practice of engraving. But first we must describe the necessary apparatus and tools.

A set of tools usually contains four or five sorts. When we speak of them generically, we call them all gravers, but when we classify them, we name the tint tools first. These are so named because tints are usually cut with them. They are made so that it is easier to cut tints with them than with the third class, which are technically called gravers or lozenge tools. This was the form used at first, and such tools still retain the name of gravers. All classes of work can be done with gravers, but it is usually found more convenient to use the tint tools for cutting tints; the gouges for cutting or "digging out" large spaces of wood; and the chisels for lowering the wood at the edges, and other parts of the picture. The gravers are useful in taking out minute dots of wood, irregular shapes, and also places with square corners. For convenience we classify and number them in the following order: First the tint tools, of which from seven to twelve in number will be necessary. These are graduated from a very fine tool—so fine that the cut it makes will hardly show when printed—to one that will cut a coarse cut, say about one-twentieth of an inch in width. The engraving (Fig. 4) shows the graduation from No. 1 to No. 11; "A" shows the side of the tool. The tint tools should be straight on the bottom, and the edges formed by the bottom and the sides should be slightly rounded, so that the tool will cut more smoothly than if the edges were square. The sides should slant from the bottom, to the top or back, which may be round or square. If the tool is no thicker at the top than the bottom, it will stick, and hang in the wood, and the lines cut, will be liable to break down in printing. A section will appear like Fig. 5. When thicker at the base than at the top, a glance will show that they will have more strength, a section appearing like Fig. 6.

Fig. 5.

Fig. 6.

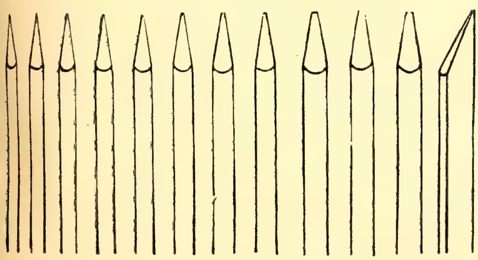

Fig. 4.—TINT TOOLS.

The second classs of tools are the gouges, or digging out tools. Of these two or three only are necessary. It is usual to have the smallest gouge make a cut that will grade next larger than the largest tint tool, and the largest gouge—large enough to take out the largest spaces. Gouges numbers 12 and 13 are large enough for general use, but if the engraver has much work requiring large spaces taken out, it would be well to add a gouge considerably larger than 13. The gouges are better for being round upon the bottom.

Fig. 7.

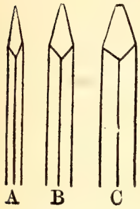
The third class of tools are the gravers, or lozenge tools, their form being lozenge in shape (Fig. 8). Two or three are sufficient. They are marked, for convenience, with the letters A, B, C, etc.

The fourth class of tools are the chisels (Fig. 9), of which one or two are sufficient. If only one is used, choose the broadest one. Mark these with Roman numerals, I, II, etc.

The number of tools used by different persons varies. Some engravers pride themselves on doing the greatest variety of work with the smallest number of tools. Others, again, have a large num-

ber, with fine gradations between. In this matter, as in most things, the mean is the wisest. A set of tools consisting of ten tint tools, two gouges, two gravers, and one chisel, form a very good set.

To these may be added some two or three oval or ellipse tools, something between a graver and a tint tool, and adapted to a large variety of work. These may be marked X, XX, etc.



A B C

Fig. 8.

In the large cities we can obtain these tools, already made, and sometimes nicely graded, but engravers usually "fit up" and grade their own tools, by rubbing them on their oil stones.

Just here we will put in a caution; in sharpening the tools, we do not apply the

Fig. 9.

sides of the tool to the oilstone; that is only done in grading and preparing them for use.

Engravers who have mechanical skill and knowledge, sometimes make their own tools, using worn out files for the purpose, the steel in files being of excellent quality, and tempered so as to fit it for engraver's use. Some of our young readers may have skill to do this themselves, and others probably have friends, with "shops" where these tools can be made, according to the descriptions we have given.

For handles to the tools you may use wood, or cork; the shape shown in Fig. 10 is one very convenient for use. The tool

Fig. 10.

should be inserted in the handle, so that it is nearly straight, bending slightly upwards, with very little of the handle below the tool.

It is necessary to have a sand bag, or leather cushion filled with sand, so full that the block will not sink into it while you are engraving—and then again it must not be so hard that the block will slide off. You may put this cushion directly on a firm table, or on a turned piece of wood made for the purpose. It is more convenient to have the cushion raised a little above the table, but not essential; but the table must be firm, and it and your cushion at such a height that you can have your body perfectly erect, whether you sit or stand while engraving.

You can commence learning to engrave without a magnifying glass and stand, but you must not try to do fine work, because you will strain your eyes, and once injured, you may suffer all through your life. The magnifying glass, should be of moderate power—an inch and a half in diameter is a very good size, and you can consult your fancy about the frame in which it is set—wood, shell, ivory, metal, etc.—though dark tints of shell, bone or rubber, are the most agreeable to use. For a stand, you may also consult your taste and means. You need an upright rod, with an arm which holds the glass, adjustable, on it. If you have nothing better, take a thick piece of wood, eleven or twelve inches long and six inches broad, and at one end, midway from the sides, put a stout wire. Take a piece of cork, and make a hole through it so that it will slide up and down this wire. Now take a smaller wire, but one that is stiff, and pierce the cork at right angles with the upright. This needs to be long enough, so that it will extend through the back of the cork an inch or two, and come forward to the front edge of the block of wood, which will also serve as a stand for the cushion. Bend the end of the wire into a round loop, just large enough to hold the magnifying glass. You need an oilstone for sharpening the tools, and this should be fine enough to make the tool smooth, while it sharpens; and should "take hold" enough to sharpen the tool quickly. Sewing machine oil, or sweet oil may be used. Put a few drops on the stone, and place the face of the tool flat on the stone. Hold it steadily, and rub from side to side, or forwards and back-

wards, as you find most convenient. You want to grind the face of the tool so that it has one smooth face, not a number of little facets; and keep your pressure so that you do not grind away the point faster than the part near the top or back of the tool. If you are successful in always holding your tool properly, you will not have much occasion for a small grindstone. But one will be useful in grinding the upper part of the face, which being wider than the point, takes longer time to grind off, on your oilstone. But be careful how you use a grindstone; you do not need it for sharpening your tools at the point; that is best done on the oilstone. A final polish is given to the tools by the use of a leather strop.

To engrave well it is necessary to keep the tools well faced, and keenly sharp. The face of the tool should be rather long than short. If too obtuse it plows its way

Fig. 11.

Fig. 12.

in the wood, rather than cuts it, and the shaving will also turn over at the point, and prevent the engraver seeing the line that is cut. Fig. 11 shows a tool too obtuse. But a tool of about the angle shown in Fig. 12 will cut cleanly, and the shaving will fall out so that it will not obstruct the sight of the engraver.

A soft brush (a tooth brush is good) is useful to brush away the small chips from the block. It must be soft, so as not to injure the lines of the engraving.

Learning to Use the Microscope—I.

As it is always well to begin at the beginning, it may not be out of place to give a few hints to those who have just purchased an instrument. When a microscope is first brought home, the purchaser is in general in a great hurry to examine it, and in this case especially the old proverb holds true, "The more hurry the worse speed." The first thing to be done is to carefully unpack the instrument, and see that the articles which accompany it correspond with the bill. In unpacking, beware of using any undue violence. Remove the packing material, but do not throw it away until you are satisfied that no little loose piece or accessory has got mixed with it. Then lift the microscope carefully out of its case. This should require no unusual force; a little patience will bring all right, whereas if you push and press, some part will very likely get bent or perhaps broken.

The next step is to free the instrument from dust, for no matter how well it may have been protected, dust will almost always penetrate during the shaking which occurs during travel. Dust is most easily removed by means of a soft camel hair pencil. Wiping with coarse or dusty cloths will infallibly scratch and injure the glasses.

We are now ready to begin the use of the microscope, and here, as in most other studies, "it is the first step that costs." After we have once made a beginning, it is easy to improve our skill and knowledge; the difficulty is to make the beginning.

It is always best for the beginner to commence with objects which are already mounted, and which consequently require no preparation to fit them for examination. It is well, therefore, to order half a dozen or more objects with the microscope, so that the material for preliminary practice may be at hand. The list should include such objects as require the most dissimilar methods of handling and illumination. Thus, for example, it should include the simplest transparent objects; objects that can only be examined by reflected light, and that require good illumination; objects that have finely marked surfaces, etc., etc. A list which will be found very interesting, which are easily procured, and which will give the beginner good practice, are: 1, a section of wood (either stained or colorless) mounted in balsam; 2, a piece of a butterfly's wing for examination as an opaque object; 3, a section of pith of plant, mounted dry, and which can be examined either as an opaque object or as a transparent one; 4, butterfly's scales, detached from the wing; 5, wing of a mosquito; 6, diatoms.

To be continued.

Bust Modelling—III.

BY ADELAIDE F. SAMUELS.

WHEN you are ready to cast the bust in plaster, the first step is to roll and pound flat on a board, a strip of clay, that will be long enough to reach from one shoulder on the bust to the crown of the head; have the strip about three inches wide, and one inch thick; stand this strip up on the bust, from the shoulder to the top of the head, bending it in to touch the neck, and letting it pass up *just behind the ear*. Press it on all the way up so that it will stay, then make another strip for the other side, and join them at the top, as shown in Fig. 8.

Fig. 8.

Now take an earthen bowl that will hold from two quarts to a gallon, fill it two-thirds full of water, and into the water pour your plaster of paris slowly, until it takes up all the water, and becomes of the consistency of cream. Stir a few times with a large spoon to get out the air, then, with the spoon, throw the wet plaster upon the face of the bust, *blowing it* into every crack and cavity, the while, until you are sure the whole surface of the face is covered. It must be done very quickly, for if the plaster is allowed to harden at all before it is thrown on, there will be air holes between the clay and it.

After the plaster has been applied, mix another bowl full, and continue to mix and lay it on, until the *whole front* of the bust has a covering of plaster as thick as the clay strips are high, that is, about three inches thick.

In Fig. 9, A shows the clay partition, and B the plaster, as it should be put on.

After the front is done, peel off the clay strips, and with a brush wet with water and clay, saturate the edge of the plaster, or all of it that rested against the clay strips; this is done to prevent the back of the mould from sticking to the front.

Now mix more plaster and apply it to the back of the bust, until that is as thickly covered as the front. Smooth it off, while wet, with a broad-bladed knife, and press it against the front, leaving the line discolored by clay and water visible between the two.

After the plaster is hard enough, which will be as soon as it ceases to feel warm, turn the bust carefully on one side, and with a large knife, cut and pull out all the clay up to the neck. Now separate the front of the plaster mould from the back. If they do not separate readily, place a chisel on the discolored line, and hit it gently with a wooden mallet; follow the line up, until the parts separate, when you can easily remove the remainder of the clay; while removing it, care must be used that the knife does not disfigure the mould inside. Now put the two parts of the mould in a tub, cover them with water, and let them remain over night. This is done to take all the *life* out of the plaster, that it may not adhere to the cast.

In the morning you can put the two pieces together, after washing off the clay that still adheres to them, and keep them in place by winding a strong cord securely around them; then mix your plaster, as before, and pour it into the mould, a bowl full at a time, and after every bowl full you must roll, and turn, and tip the mould until the plaster penetrates into every part of it; do this until the plaster inside the mould is about three inches thick, when nothing more can be done that day, as the cast must have time to harden, or you will be likely to break it.

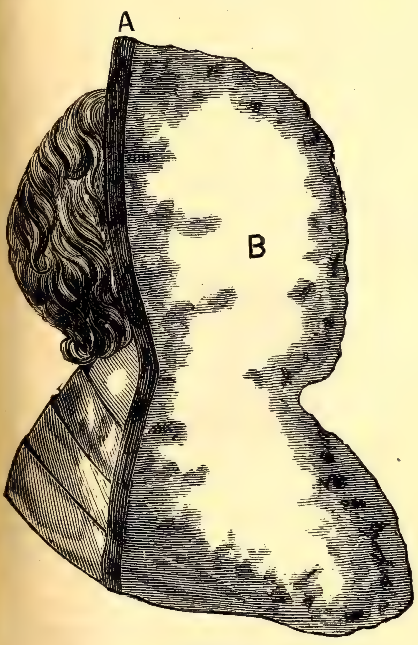


Fig. 9.

The next day you can get out your mallet and chisels.

Plaster workers have a particular kind of chisel, like that shown in Fig. 10. If you live near a blacksmith, you could easily have a large and a small one made; if not, you can make ordinary chisels answer.

With your mallet and largest chisel, begin at the lower edge of the bust to "*chip off*" the mould. It is delightful to see the face you worked so long at in the clay, appearing in the plaster, as the mould disappears. Do not *dent the cast with the chisel* if you can possibly avoid it. If you should do so, mix a little fresh plaster and fill the dent with it. You must use a small chisel to do the fine chipping about the face, and be *very careful* not to disfigure the features. If you should *break* any

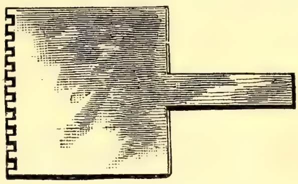

Fig. 10.

part of it, you can mend it again by making the edges rough, and joining them with wet plaster.

After the mould is all off, place the cast where it will dry, and give all your attention to the *Pedestal* to mount it on. You can buy one for a trifle at the image-caster's, but if you prefer to make one, you must proceed in the following manner. Model in clay one shaped like Fig. 11, having the circumference of the bottom about the same as the circumference of the head. After it is modelled, give it a covering of plaster two inches thick, for the mould; then remove the clay, and after washing the mould and letting it

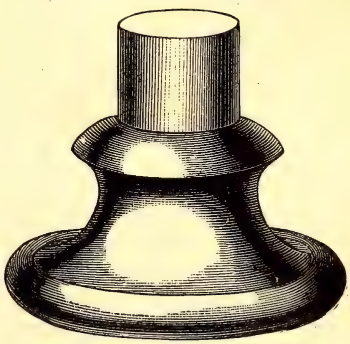

Fig. 11.

stand a while in water, fill it full of wet plaster; when that is hard, chip off the mould as before, and you have your pedestal. Insert the top of it in the opening in the bottom of the bust, be sure that it will *stand straight*, then fill in all around it

with wet plaster, and let it remain until perfectly hard.

When the bust is *quite dry*, get some very fine sandpaper and rub off the line caused by the joining of the mould; then give it a few finishing touches and it is done.

To make any number of the same bust, a *piece mould* must be constructed. They are very complicated, and difficult to make, and are never attempted but by professional casters.

How to Grind Convex Lenses.

BY R. M. BAILEY.

TO many persons the process of shaping and polishing glass lenses seems beyond the powers of those who have not the acquired skill and the mechanical appliances of the professional optician. But this is not the case. Any one of fair mechanical ability, and with means that are to be readily obtained almost anywhere, can produce good magnifying glasses of any desired powers within certain limits. Perhaps it is not too much to say that first-class convex lenses can be made by any reader of THE YOUNG SCIENTIST, after a little practice. We will show how this can be done.

Any turning lathe having the end of the mandrel hollow, can be used as a grinding and polishing machine, and is all the machinery that is required. The Lester scroll saw, with lathe attachment, answers very well for grinding microscope lenses.

Decide upon the focal length of the lens you wish to grind, and also whether it shall be plano-convex or double-convex. If plano-convex, set a pair of dividers to half the focal length required; if double convex, set them to the whole focal length. We will suppose that you wish to make a plano-convex lens of one-inch focal length, which will magnify ten diameters. Set the dividers to half an inch, and upon a piece of sheet brass, or zinc, strike a quarter or third of a circle. With shears or a narrow cold chisel, cut out the inner part of the circular segment, finishing, with a half round file, carefully and exactly to the mark. You thus have a concave gauge like Fig. 1.

Next procure a strip of thick saw blade or other flat steel, not over an inch in width, and long enough to be conveniently handled. An old chisel will answer well. Grind one end to a convex shape that will exactly fit the concave gauge, giving it a sharp cutting edge of large angle, not less

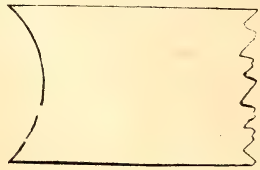

Fig. 1.

than sixty degrees, rounding off the other angle, so that on holding it edgewise, the edge will appear like Fig. 2. Fig. 3 represents the edge of this gouge, as we will call it, when completed. It must fit the concave gauge so exactly that on placing the edges together no light can be seen between them. The curve must be the

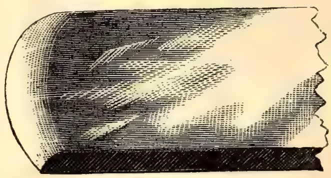

Fig. 2.

same at every point in both gauge and gouge, which may be proved by fitting them together at different angles.

This gouge is to be used in making the next tool, which is a concave grinder or lap required in polishing the lens. Take a block of hard wood, plane one side smooth, and with an inch bit bore a hole

Fig. 3.

half an inch deep in the planed surface. Then in the centre of this hole bore another hole through the block, this last hole being a little larger than the hole in the mandrel of the lathe. These holes must be bored quite perpendicular to the planed surface of the block. Fig. 4 repre-

sents this block cut through the middle of the hole, to show how it is bored. Lay this block upside down upon some smooth surface, either wood or metal, preferably the latter. Now melt some block tin or tinsmith's solder on a ladle, and pour it into the mould thus placed, taking care to hold the block in place while pouring.

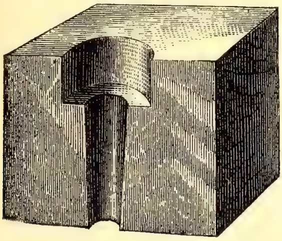

Fig. 4.

On removing the cast metal from the mould, it will present the appearance of a bolt with a circular head and without a screw thread. Centre this as exactly as possible in your lathe, putting the spur centre into the smaller end, and turn the smaller part into a spindle like that of the spur centre, so that when the spur centre is removed the tin spindle will fit into the mandrel smoothly and tightly in its place. Have it go in far enough so that the tin head will rest firmly against the end of the mandrel. A few trials during the process of turning will enable this to be done with sufficient exactness. If this has been properly done, on revolving the mandrel the end of the tin which projects

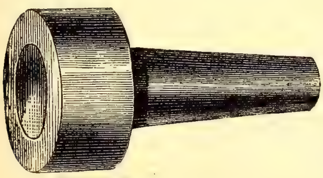

Fig. 5.

from it will be free from noticeable "wabbling" motion. Then set the slide rest of the lathe squarely in front of the tin, rest the convex gouge upon it, place the cutting edge against the middle, which is marked by the tail-stock centre, set the lathe in motion and turn the metal out until you have a smooth concavity in the end of the tin a little larger in diameter than the proposed lens; then dip a piece of slightly moistened flannel cloth into "putty powder," and polish this concavity, being careful not to polish it out of shape. This concave surface must be so true that when the convex gouge used as a gauge, is placed squarely against it, no light can be seen passing under it. Fig. 5 represents this tin polisher when finished.

The last preliminary to the grinding of the glass is to turn a piece of hard wood into the shape of Fig. 5, except that the end must be plane instead of concave, and the head should be turned down to the diameter you propose to give the lens.

To be continued.

Editorial Notes.

Our New Dress.

THE YOUNG SCIENTIST was commenced January, 1878, as a journal of twelve pages. The type was clear and handsome, but was a size larger than that used in journals of a similar class—the object being to relieve the eyes of the reader as much as possible. The journal was essentially an experiment. It was devoted wholly to *practical* matters—eschewing theory as much as possible. Its object was to describe those facts in science which could be easily verified by experiment, and to tell how to perform the experiment; and as a necessary adjunct to this all those arts most affected by amateurs and young people formed important subjects for discussion. Our first idea was that twelve pages per month would be ample, but ere long we found that additional pages became necessary, and towards the close of the year the range of subjects in which our subscribers showed an interest, and the amount of matter pressed upon our attention, demanded more room. We therefore not only added four pages, but reduced the size of the type—the result being that the amount of matter contained in the number for January, 1879, was more than one-half greater than that contained in the number for January, 1878. The pages were also elec-

trotyped, so that back numbers for the year 1879 might always be on hand.

These changes caused considerable delay and annoyance, and the result was far from satisfactory. Although our readers, wherever heard from, expressed themselves more than satisfied with the new form of the journal, we did not feel pleased with it. The type was not clear enough to suit us, and the general arrangement seemed to us capable of still further improvement. We therefore had a new font of type made expressly for this journal. The style is known as *Scotch face*, and while it is a full size smaller than the type used last year, it is much more readable, the *face* of the letters being actually larger! This seems almost a contradiction in terms, and the statement will no doubt puzzle many of our readers. We regard the production of this type as one of the marvels of the art, since it enables us to give a very much larger amount of matter in the same space, and is at the same time actually more easily read!

Now that we have completed this number under our new arrangements, we feel confident that things will go smoothly, and we certainly feel also that we have reason to be proud of the appearance of our little journal. We trust that our readers will appreciate this effort to give them the best journal possible, irrespective of labor or expense, and will excuse the unfortunate delays which have marred the commencement of the new year.

Special Offer to Our Subscribers.

THE new edition of the "Amateur's Handbook of Practical Information" has been greatly enlarged, and it now contains the very cream of the larger books on the same subject. We have the strongest possible evidence of its real value in the fact that large numbers of the first edition were sold to persons who had seen copies of it in the hands of their friends. We have had a few copies substantially bound in cloth, with gilt titles, the price of which is 30 cents; and to enable our old subscribers to procure the book easily, we will send a copy to every one that will procure us a *new* subscriber, and remit fifty cents. This offer is open only to subscribers whose names are now on our books, but any one sending two names and $1.00 can have the book.

Special Notice.

TOWARDS the close of last year, we offered to our old subscribers the privilege of obtaining their own subscriptions free, by sending the names of two *new* subscribers. This was virtually giving the YOUNG SCIENTIST for one year for 33⅓ cents. We have expended so much in improving the journal, however, that we cannot afford to do this now, and the offer is accordingly withdrawn. Our club and premium lists will still be found to be quite as liberal as those of any journal in the country.

Numbers for 1878.

WE regret to say that the numbers for March, 1878, are entirely exhausted, so that we can no longer supply full sets of the first volume in sheets. We have a few copies of Vol. I on hand, bound in cloth, with gilt title, which we offer for $1.00 by mail, postpaid.

BOOK NOTICES.

The Amateur's Handbook of Practical Information for the Workshop and the Laboratory. Second Edition; Greatly Enlarged. Price 15 cents. New York: Industrial Publication Company.

It is but a short time since we noticed the first edition of this work, and the rapidity with which this edition has been exhausted is very good evidence of the value of the book, as well as of the need for such a manual. The present edition has been greatly enlarged, so that it now contains the cream of the practical recipes found in the larger books and cyclopædias. Owing to the large circulation which it has attained, the publishers are enabled to give a good deal for the money.

The Heavens for March.

BY BERLIN H. WRIGHT.

PLANETS.—MERCURY will be brightest as an evening star March 26-29, when he will be about 19° from the sun, setting about 9° north of the sunset point, as follows:

March 23—7h. 40m. evening.
March 26—7h. 50m. "
March 29—7h. 57m. "
April 1—7h. 58m. "

On the 29th he sets 1h. 36m. after sunset, and 5 minutes after the close of twilight. If clouds do not prevent, he may be easily seen from March 20 to April 5. There are no stars brighter than fifth magnitude in his vicinity.

VENUS will be a brilliant evening star throughout the month, setting as follows:

March 10—7h. 49m. evening.
March 20—8h. 13m. "
March 30—8h. 38m. "
April 10—9h. 4m. "

She will move eastward past the stars of the constellation Pisces, the Fishes, until the 27th, and after that date in Aries, passing Neptune April 1, being about 2° north of him. She will be about 5½° south of the Moon on the 25th.

MARS will be in the constellation Sagittarius, the Archer, until the 20th, and afterward in Capricornus. On the 18th he will be directly south, about 5°, of the three stars which mark the head, or, rather, one of the horns, of the Goat. This is the only cluster by which the constellation can be readily recognized. The two extreme stars are of the third magnitude, and about 4° apart, being nearly in a north aud south line. The middle star is dimmer, being of the fourth magnitude. He rises as follows:

March 10—3h. 54m. morning.
March 20—3h. 41m. "
March 30—3h. 26m. "
April 10—3h. 6m. "

He will pass south and very close to the Moon on the 17th. This conjunction will be witnessed in Europe as an occultation.

JUPITER may now be seen in the east as a morning star, rising as follows:

March 10—5h. 32m. morning.
March 20—4h. 58m. "
March 30—4h. 4m. "
April 10—3h. 47m. "

He is moving eastward past the stars of the constellation Aquarius, and during the latter part of March and first of April will be about 10° directly south of the ⅄, a plain figure which marks the northern limit of that constellation. He will be about 3¼° south of the Moon on the 20th.

SATURN, being in conjunction with the Sun on the 26th, will be unfavorably situated throughout the month. After March 26 this planet will be seen in the east as a morning star.

URANUS passes the meridian as follows:

March 10—11h. 1m. evening.
March 25—10h. 0m. "
April 10—8h. 55m. "

NEPTUNE is too near the Sun to be observed.

METEORS.—Meteoric stones have fallen with more or less regularity upon the following dates: March 6, 12 and April 1.

OCCULTATION OF *Alpha* SCORPIONIS (ANTARES) BY THE MOON.—The brilliant red star, Antares, will be occulted by the Moon April 10, in the morning. The occultation will be visible throughout the Southern States south of Virginia, north of which it will be a very close approach, the star being north of the Moon. The nearest approach in New York occurs about 2h. 27m. morning, when the star will be about ⅛° north of the Moon's northern limit.

POSITIONS OF THE PRINCIPAL CONSTELLATIONS AND STARS FOR MARCH 15, 9 P. M.:

East of the Meridian—Leo Major and Minor, Virgo, Libra Bootes and Berenice's Hair. Stars—Regulus, Spica, Denebola and Arcturus.

Near the Meridian—Cancer and the head of Hydra.

West of the Meridian—Gemini, Canis Major and Minor, Auriga, Taurus, Orion and the Hare. Stars—Castor, Pollux, Procyon, Sirius, Capella, El Nath, Betelguese and Rigel; also the following clusters: The Kings in Orion, and the Hyades and Pleiades in Taurus.

Towards the Pole—Above, the Great Bear's Head; to the right, Ursa Minor, containing the Little Dipper, the body of the Great Bear, containing the Great Dipper and Draco; to the left, Cassiopeia, containing the Chair, and Perseus.

EPHEMERIDES OF THE FIRST MAGNITUDE, STARS, ETC., FOR MARCH 20:

		H.	*M.*	*Amplitude.*
Alpheratz,	sets,	8	1 eve.	39° +
Mira,	sets,	8	9 eve.	5° —
Algol,	sets,	0	20 morn.	59° +
Pleiades,	sets,	11	16 eve.	32° +
Aldebaran,	sets,	11	24 eve.	22° +
Capella,	sets,	3	27 morn.	71° +
Rigel,	sets,	10	47 eve.	11° —
Betelguese,	sets,	0	25 morn.	10° +
Sirius,	sets,	11	48 eve.	22° —
Procyon,	in meridian,	7	41 eve.	7° +
Regulus,	in meridian,	10	9 eve.	17° +
Spica,	rises,	8	3 eve.	14° —
Arcturus,	rises,	7	6 eve.	27° +
Antares,	rises,	0	13 morn.	36° —
Vega,	rises,	9	46 eve.	56° +
Altair,	rises,	1	26 morn.	11° +
Deneb,	rises,	10	49 eve.	69° +
Fornalhaut,		invisible.		

By the aid of the above, the amateur observer will have little trouble in recognizing all of the principal stars, clusters and constellations.

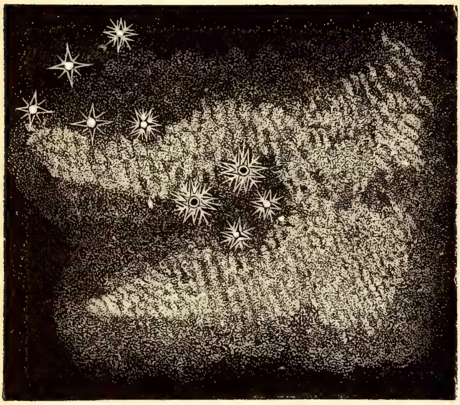
ALGOL—MINIMA:

March 3—1h. 4m. morning.
" 8—6h. 42m. evening.
" 23—0h. 50m. morning.
" 25—9h. 40m. evening.

ORION AND ITS TELESCOPIC OBJECTS.—In this constellation there are seventy-eight stars—

two of the first magnitude, four of the second, three of the third, and the remainder of dimmer grade. There are three small and one great nebulæ, three clusters, and twenty-six double stars in this remarkable constellation. We will only call attention to those objects which are of the greatest interest, and which come within the scope of a 3½-inch glass.

The greatest nebula is 42 Messier, situated about 4° directly south of the middle star of the belt, or Ell and Yard. A line from Rigel to the lowest star in the belt, will pass very close to the nebula, it being somewhat nearer to the dimmer star. It may be seen with the naked eye on a moonless night, as a dull patch of light. In the illustration will be seen the appearance of the Great Nebula, viewed with a 3-inch telescope and a power of 76 diameters.



GREAT NEBULÆ IN ORION.

In the opening on one side is situated the stars which form the celebrated "Trapezium of Orion," upon which so many telescopes have been tested. We believe the best instruments reveal nine stars in the Trapezium. If the light-gathering power of a 3½-inch glass be good, five ought to be seen; with a 3-inch glass, four; and with a smaller aperture only three. Herschel, with his great reflector, hoped to resolve this nebula, but failed, and until the great spectroscopist, Huggins, proved it to be a gaseous collection, it was believed to be resolvable.

Rigel, the bright star below the belt, is a noted double, and a severe test for small telescopes. The secondary is of the seventh magnitude according to Proctor, and ninth according to Darby. Distance, 9.5″. We have seen the companion with a 3-inch aperture, and it is believed that 2¾ inches will do it. A moderately high power should be used. A 3-inch glass will show the northernmost star of the belt double, and a somewhat larger instrument will show the southernmost to be also double.

On a line from Betelguese to Aldebaran, and about 6° from the former, is a cluster of three stars—one 4th magnitude, and two 5th magnitude. The brightest one is the most northern, and a 3-inch glass shows it double; a 3½-inch, triple.

About one degree from the lowest star in the belt, or Ell and Yard, and on a line from that star to the Great Nebula, is situated a beautiful and easy multiple star—Sigma Orionis. A good 3½-inch objective with a high power will show this star octuple, and smaller instruments fewer—sextuple, quintuple, etc. The astronomer, Struve, saw fifteen stars in this group.

Penn Yan, N. Y.

Practical Hints.

Optical Delusion.—Take three differently colored wafers—red, violet, and orange—place them upon a large piece of white paper, in a triangular form; hold the paper in a strong light, and fix the eyes upon the wafers, gazing upon them steadily for two minutes; then turn them away from the wafers to a blank part of the paper, and you will see three spectral wafers, but the colors will be different; the red wafer will now be represented by a green one, the violet by a yellow, and the orange by a blue.

Japanese Matches.—Lampblack, 5; sulphur, 11; gunpowder, from 26 to 30 parts—this last proportion varying with the quality of the powder. Grind very fine, and make the material into a paste with alcohol; form it into dice about one-quarter of an inch square, with a knife or spatula; let them dry rather gradually on a warm mantelpiece, not too near a fire. When dry, fix one of the little squares into a small cleft made at the end of a lavender stalk, or, what is better, the solid straw-like material of which housemaids' carpet-brooms are made. Light the material at a candle; hold the stem downward. After the first blazing off, a ball of molten lava will form, from which the curious coruscations will soon appear.

Decoration of Zinc.—A chemical process for covering zinc with colored coatings has lately been described by Dr. L. Stille. The articles of zinc are first brightened by scouring with quartz sand, moistened with dilute muriatic acid, putting them quickly in water, and then carefully wiping them dry with white blotting paper. To ensure success, however, it is necessary to employ zinc as free as possible from lead, and to have it as bright as a mirror. When these conditions are fulfilled, the metal may be coated with a variety of beautiful colors by immersion in a solution of alkaline tartrate of copper for a shorter or longer interval of time, depending on the color that is desired.

Varnish for Stained Woods.—A solution of four ounces of sandarac, one ounce gum mastic, and four ounces shellac, in one pound of alcohol, to which two ounces oil of turpentine is added, can be recommended as a varnish over stained woods.

Cement for Wood and Iron.—A cement made of oxide of lead and concentrated glycerine, unites wood to iron with remarkable efficiency. The composition is insoluble in acids, is unaffected by the action of moderate heat, sets rapidly, and acquires an extraordinary hardness.

M. Camille Flarumarion, the well-known French meteorologist, having been led to believe that the moon contains inhabitants, is making an effort to procure funds to enable him to construct a refracting telescope sufficiently powerful to show them. The amount which he estimates as necessary is $200,000.

Black Varnish for Cast Iron.—For those objects to which it is applicable, one of the best black varnishes is obtained by applying boiled linseed oil to the iron, the latter being heated to a temperature that will just char or blacken the oil. The oil seems to enter into the pores of the iron, and after such an application the metal resists rust and corrosive agents very perfectly.—*Amateur's Handbook.*

Imitation Rosewood.—Boil one-half pound of logwood in three pints of water till it is of a very dark red; add one-half ounce of salt of tartar. Stain the work with the liquor while it is boiling hot, giving three coats; then, with a painter's graining brush, form streaks with the following liquor: Boil one-half pound of logwood chips in two quarts of water; add one ounce pearlash, and apply hot.

Cement for Steam Joints.—Take sal-ammoniac, two ounces: sublimed sulphur, one ounce; fine cast iron turnings, one pound; mix in a mortar, and keep dry. When to be used, mix with twenty times its quantity of clean iron turnings or filings, and triturate the whole in a mortar; then wet with water until of proper consistence. A red putty for steam joints can be made of stiff white lead worked well in red lead powder.

The latest experiments with guns of the largest size are quite interesting. The highest velocity imparted to the shot is 1,626 feet per second. This is equal to a mile in a very little more than three seconds (3.2 seconds). The pressure on the interior of the gun was 19½ tons. In previous experiments, however, where a less velocity was obtained, the pressure was 21 tons. The increased velocity is attributed to the greater size of the grains of powder used, and it is laid down as an axiom that the larger the gun the larger must be the grains of powder.

Varnish for Basket Ware.—The following varnish for basket work is said to dry rapidly, to possess sufficient elasticity, and to be applicable with or without admixture of color: Heat 375 grains of good linseed oil on a sand bath until it becomes stringy, and a drop placed on a cold, inclined surface does not run; then add gradually 7,500 grains of copal oil varnish, or any other copal varnish. As considerable effervescence takes place, a large vessel is necessary. The desired consistency is given to it, when cold, by addition of oil of turpentine.

To Make Corks Air-tight and Water-tight.—A German chemical journal commends the use of paraffine as the best method of making porous corks gas-tight and water-tight. Allow the corks to remain for about five minutes beneath the surface of melted paraffine in a suitable vessel, the corks being held down either by a perforated lid, wire screen, or similar device. Corks thus prepared can be easily cut and bored, have a perfectly smooth exterior, may be introduced and removed from the neck of a flask with ease, and make a perfect seal.

Black Varnish for Optical Work.—The external surfaces of brass and iron are generally blacked or bronzed with compositions called lacquers. The insides of the tubes of telescopes and microscopes should be coated with a dead black varnish so as to absorb the light and prevent any glare. The varnish that is generally used for this purpose consists of lampblack made liquid by means of a very thin solution of shellac in alcohol, but such varnish, even when laid on warm metal, is very apt to scale off, and thus produce two serious evils—the exposure of the bright metallic surface, and the deposit of specks on the lenses. It will therefore be found that lampblack, carefully ground in turpentine, to which about a fifth of its volume of gold size or boiled linseed oil has been added, will adhere much more firmly. The metal should be warm when the varnish is applied.—*Amateur's Handbook.*

Stretching Tracing Paper.—The thin, transparent tracing paper, used by architects and draughtsmen, can be stretched or be mounted so as to give a fine even surface, on which water-coloring and shading can be done as easily as upon mounted paper. Cut a piece of drawing-paper the size of the drawing-board; gum the upper surface edge of the board, about half an inch in width; spread the tracing paper carefully over the drawing, and smooth down on the gummed edge; then turn the sheet back, and gum the remaining three edges of the board; bring over the tracing paper, and smooth down the edges; do not pull or twist the sheet, so as to get it tight or severely strained, but get the edges well held down by the gum. After the gum has dried, a clean sponge, well saturated with water, may be passed over the entire surface, except on the gummed edges. The tracing-paper expands and blisters all over, but in a few minutes the dampness evaporates, and a beautiful surface is presented, similar to a transparent slate. The tracing can now be colored or shaded as on drawing paper, and any blots or errors can easily be washed out.

Exchanges.

Yearly subscribers to the YOUNG SCIENTIST have the privilege of inserting three exchanges (or one exchange three times) during the year. This privilege is strictly confined to *exchanges; buying and selling* must be carried on in the advertising columns, where the charge is 30 cents per line. Each exchange is limited to thirty words, making about four lines, and in order to receive attention must be written on a slip of paper by itself. We file all letters received and have no time for copying out exchanges and queries.

As we desire to make the journal of the utmost value to *all* and not merely to serve the interests of individuals, we shall strictly adhere to these rules, which are certainly liberal, giving as they do advertising to the value of $3.60 free to each subscriber.

A combination scroll saw and lathe, cost $16.00, to exchange for a printing press or type. C. H. Parker, Coldbrook Springs, Worcester Co., Mass.

A bill boka board, in perfect condition, cues and balls, cost $8 very recently, in exchange for a scroll saw in good condition. S. F. Allen, 47 W. 12th st., city.

Scientific American, 1870 to 1878, over 450 Nos., not bound, to exchange for good Natural History, opera glass, watch, gun, or offers. J. T. Bell, Franklin, Pa.

Groff's Model Suburban Architecture wanted in exchange for Nicoll's Railway Building, Templeton's Practical Examination of Steam and Steam Engine, and Colburn's Locomotive Engine. All entirely new. F. H. Jackson, Angelica, N. Y.

Wanted, a small turning lathe, state what is wanted in exchange. Ralph A. Pillsbury, P. O. box 555, Belfast, Me.

To exchange, beautiful rose, milk, greasy and smoky quartz, graphic granite, orthoclase, etc., for aboriginal relics, coins, or other minerals. Prof. C. L. R. Wheeler, Bedford, N. Y.

A collection of invertebrate fossils, accurately labeled and worth $225, to exchange for good microscope. The instrument must be of modern make, and in first-class condition. S. Calvin, Iowa City, Iowa.

A collection of foreign and dept. stamps, or a large collection of bird eggs of the Southern States, for a set of drawing instruments or books on plain and ornamental penmanship. Address Q. R. S., Mt. Pleasant, Washington, D. C.

Wanted almost anything in exchange for a complete set of cabinet maker's tools. The chest alone is worth twenty-five dollars. Address Mr. Clark, P. O. box 37, Brooklyn, N. Y.

For exchange, two good dial telegraph instruments, and two good Morse telegraph instruments, for printing press or bracket saw. James Scott, 20 Patchen ave, Brooklyn.

A card printer, type and cards worth $1.50, and the book "His own Master" will exchange separately or all together, books, or offers. Geo. R. Simpson, Janesville, Iowa.

A stationary cylinder steam engine, or hardware goods in exchange for an electric call bell. L. J. Otis, 973 Prairie Ave., Chicago, Ill.

Wanted for a good Gundlach No. 4 (¼) Objective, a 1½ or 2 inch Objective of wide angle. C. Onderdonk, Brooksburg box, Madison, Ind.

A spy glass costing five dollars, to exchange for a companion scroll saw and turning lathe in good condition. John Buck, Brazil, Clay Co. Ind.

Forty good photo-lantern slides, plain and colored, for a good printing press and outfit; or a small screw cutting lathe; or first class microscopic objectives, or offers. Wm. R. Brooks, Phelps, N. Y.

Wanted, a small rifle, in good order, bore 22-100, for a telegraphic key and sounder, instruments are made of brass finely wrought, mounted on a japaned iron base. Louis E. P. Smith, 6 Alpine st, Boston, Mass.

Ferns, mounted or unmounted, for Northern species of same. List of those on hand and those wanted sent on application. Maj. R. H. Wildberger, Ky. Mil. Inst., Farmdale, Ky.

Two good business lots, central, in Ellsworth, Kan, for good microscope, accessories and books, chemical balance, or gold watch. Wm. Zimmerman, 114 Dearborn st, Chicago, Ill.

To exchange, a collection of 500 rare stamps, with book which cost $1.50. The whole worth about $7.00. State offers. Albert N. Webster, 106 South Park ave, Chicago, Ill.

Hinkley knitting machine, worth $40, for a watch or breach loading shot gun, Harry Holden, Black Earth, Dane Co. Wisconsin.

One dozen (assorted) mounted objects for microscope, cost $2.50 (By J. W. Queen & Co.) for useful books on any subjects, or old U. S. coins. W. M. Stribling, P. O. box 350, Circleville, Pickaway Co, Ohio.

Cabinet mineral specimens, for Masonic publications, or other instructive books. Light reading not wanted. J. P. Clough, Junction P. O., Lemhi Co. Idaho.

Swiss watch lathe, brass, steel shaft and box, cost $25. Also a gear cutting lathe nearly complete. Exchange for minerals, microscopic slides and books. H. A. Cutting, Lunenburg, Vt.

Twelve dollars worth of parlor tricks, very best make, in exchange for a good microscope or a scroll saw with lathe attachment, of equal value. Prof. C. H. Houghton, Middleboro, Mass.

Book on magic, cost $2.50, for back numbers Young Scientist, and foreign stamps. Omega, Post Warrensburg, Mo.

Wanted, Parrishes Pharmacy and chemicals. State what is wanted in exchange. C. O. K., 1520 Fairmount Ave, Phila.

Stereoscopic views of New York city and vicinity, in exchange for fossils from the Western states and terri tories. T. P. Wendover, P. O. box 1862, N. Y. city.

Chemical apparatus or balance, spy glass or saw wanted, in exchange for novelty printing press, with sixty fonts of type. Alex, 151 East 33d st, N. Y.

Microscope worth $7.00, and cabinet with forty good slides; for better instruction or other educational apparatus. Particulars on application. Arthur Hobart, Penn Yan, N. Y.

Wanted a copy of Bourne's Treatise on the Steam Engine, for a full set (7 vols. bound) of Technologist, cost $19.25. W. J. Allen, 256 Twenty-second st, Bkyn.

Wanted, a three wheel "velocipede" large size, state what is wanted in exchange. Peter J. Murray, box 743 Wilkesbarre, Pa.

To exchange, one Bunsen and two Smee batteries; for books on electro-metallurgy or quantative or qualitative analysis. A. W. Palmer, care of Watch Co. Springfield, Ill.

A pistol in good order, cost $3.00, in exchange for an electric bell. A. W. Honywill, 217 Cabot st, Boston, Mass.

Collection of over 500 rare stamps, including Ecuador Cape of Good Hope, Barbadoes, Honduras, etc., in exchange for microscope, minerals, or scientific publications. Jas. G. Kitchell, 345 Race st, Cincinnati.

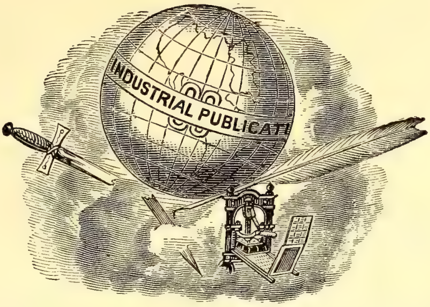
Music box, printing press, cost $35, and complete out fit for cutting stencil plate for marking clothing, cost $25, for boiler large enough for ¼ horse power. Geo A. Battles, Westminster, Mass.

Three-quarter portrait camera tube, with box and tablets all new; for books on science, medicine, history, or travel, or microscopic slides. J. S. Mason, Medina, Ohio.

Wanted, a printing press or set of draughting instruments for a C cornet (worth $30.00) or Queen's Universal Household Microscope and accessories. G. E. T., Box 475, Westboro, Mass.

The Young Scientist

SCIENCE IS KNOWLEDGE.



KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, APRIL, 1879. No. 4.

A Dollar with a Hole in It.

BY A. W. ROBERTS.

SOME two years after my tub adventure, my father obtained for me a situation in a law office in New York, where I was to receive a dollar a week: yes! a whole dollar—a dollar with a hole in it, and a silk cord through it. When my employer, Mr. Emerson, placed it about my neck smilingly, I knew that my first week at law was an established success. All the way home I wore it as a watch, taking it out every few blocks to admire, arriving home early, for I ran all the way, so anxious was I to give to my mother my first dollar earned in New York city. But when she told me I might keep it, the news was too much for me, and I had to make a bolt for the stable, to give vent to my happiness, and proclaim my good fortune to all the cows.

One day shortly after this, when examining the apple stands in John street, to ascertain if any of the two-cent apples had been placed in the one-cent apartment, I beheld an object that riveted my attention at once. In a window of a seed store was what appeared to be a glass case filled with water, and in the water were beautiful green plants and many kinds of live fish, all new to me. Every morning, noontime and after office hours, I visited the seed store, for several weeks, but what puzzled me greatly was that no one ever seemed to change the water or pay the slightest attention to the fish, yet the plants grew longer every day, and the fish more robust.

After reaching home, I dug up a handful of earth worms, putting them in damp moss to thoroughly rid them of all earthy matter. These I offered to one of the salesmen of the store, to feed the fish; he

was greatly pleased, and told me the different names of the fish, and that "you don't have to change the water because the plants keep it pure."

I wrote it down, I repeated it to myself, it was constantly in my mind, "You don't have to change the water, because the plants keep it pure." Here was a new revelation in plant life, and I thought to myself what very pure water must be contained in water-cress beds.

I was sure this plant must be foreign and costly, so taking more worms, I ventured to ask him if he would sell me a dollar's worth of the plant, at the same time displaying my dollar with a hole in it; but he could not spare any without upsetting the "balance."

Where did he obtain it?

He thought it came from Long Island, and could sell a good deal of it if he could obtain it.

What was the name of it?

Ranunculus aquatilis.

Would he please write it down, and didn't he know of an easier name? So he wrote, "Common name—White crowfoot; scientific name—*Ranunculus aquatilis;* is semi-aquatic; flowers in June; found growing in ponds on Long Island."

I said thank you, good day, and left with a feeling of fullness. Here was more light or more darkness on the subject of plants.

That afternoon Mr. Emerson noticed me reading the paper over and over, looking very much puzzled, and being very quiet; at last he asked me what was the matter, so I laid the whole case before him. I then learned that all plants have both a common and a scientific or botanical name; that the scientific name is the same all over the world, and that the common name is that by which it is known in the common language of the country or locality. For instance, the *Ranunculus aquatilis* belongs to the family of buttercups, and bears a strong resemblance to our field buttercup when growing out of the water; and for this reason I have known it to be called the water-buttercup, which I think is a much better name than the common name it bears in England, of crowfoot, as its leaves are but a poor suggestion of a crow's foot. Still that is the common name it goes by with English botanists, who first described and classified it. He also informed me that "semi-aquatic" meant growing or adapting itself either to land or water.

About this time I was given two weeks' vacation, and determined to invest all my dollar in visiting the ponds of Long Island, till I found the crowfoot. In this I was successful, and soon sold five dollars worth, with which money my first glass case (or, as I learned to call it, aquarium,) was paid for.

Dealers in stock began to spring up in all parts of the city, and the demand for aquatic or water plants increased daily, so that I found it profitable, as well as healthful and pleasant, to go into the business, and get back to the woods and flowers.

Every variety of plant I obtained was thoroughly tested to ascertain its oxygenating qualities; in this way I soon became an expert on plants and their habits, and orders came in faster than I could fill them, so that in a short time the dollar that I had first expended in search of plant knowledge was multiplied many times.

Dealers in aquatic plants are still telling the same old vague story of so many years ago, "You don't have to change the water, because the plants keep it pure." They seldom inform their customers *why* or *how* the plant life sustains the animal life contained in the aquarium, and very many of them do not know and do not care. I know a dealer who sells hundreds of bunches of plants a year; one day I asked him, in a careless, off-hand way: "W———, what on earth is carbonic acid gas?" His reply was that he neither knew nor cared what "carbolic" acid gas was. In his establishment are many varieties of plants; some of them are of no value, but they possess a bright green color, and sell well, and *rot* well when placed in an aquarium, so that after a beginner has bought several lots of these plants, he gives up in despair Many dealers say they do not want the plants and fish to live too long, as they cannot sell as much stock.

So I have carefully prepared a list of reliable plants, with drawings which I

Fig. 1.—MERMAID WEED.

made from life. This will also serve as a guide to those who collect their own plants.

Proserpinaca. Mermaid Weed; also er-

Fig. 2.—WATER THYME.

roneously called by dealers Millfoil. In the illustration (Fig. 1) I have shown it in its summer leaf, when growing out of water, gradually becoming finer as it becomes submerged with water towards winter, by which time it is in its full aquatic dress. Found in ponds that dry up in summer time. Only reliable for winter use. Does best in low temperature. Of a reddish green color to a bright light green.

Anacharis Canadensis. Water Thyme. (Fig. 2). Found growing in slow flowing streams. Is of a rich dark green color. Only of use in winter time. Requires a low temperature; not too much light, or it will spindle. After planting, heap up plenty of gravel stones on the rooting end of the bunch. It is difficult to root in the aquarium, and requires much coaxing.

Nitella flexilis (Fig. 3). Found in ponds and streams. Does well all the year round;

Fig. 3.—NITELLA FLEXILIS.

high or low temperature. Will grow without roots.

Fontinalis gigantea and *Fontinalis antipyretica.* *F. gigantea* is of a very rich deep green, with a brownish color towards the base of the plant. Found growing in springs attached to rocks. Will live and

grow after being detached. In one tank it lived for over four years.

F. antipyretica (Fig. 4). Found in springs and lakes. Is of a light green color, and is very hard to kill. I have thrown it out of the aquarium into the garden, where it was exposed to the hot sun all summer,

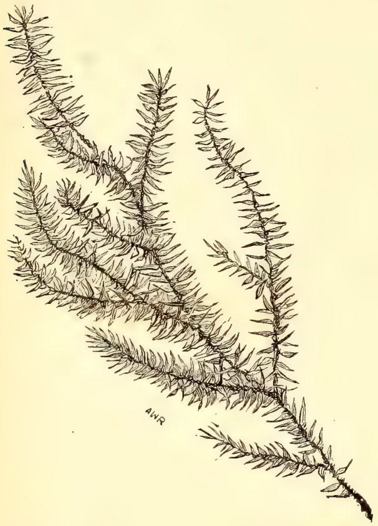


Fig. 4.—FONTINALIS ANTIPYRETICA.

but when placed in the water it started forth into a bright green mass again. All the varieties of this order of plants I consider to be equal to any plants now in use, they will stand so much abuse, particularly all the small leaved varieties, that grow in lakes and standing water. They will stand a high or low temperature, and flourish both winter and summer.

How to Grind Convex Lenses—II.

BY R. M. BAILEY.

HAVING selected a piece of crown glass, cut from the plate a piece somewhat larger than the proposed lens, and with a pair of nippers trim it as nearly as possible to a circular shape. The glass must be cemented to the end of the wooden centre. For this purpose use a cement with shellac as a basis, called by jewelers black cement. It is sold in the form of sticks. Melt the end of this in a lamp flame, and smear it on the wood, thinly but evenly. Pick up the glass and hold it in the lamp until it is quite hot, and then holding the cemented end of the wooden centre in the flame so as to remelt the cement, place the hot glass on it; press them firmly together, centering the glass on the wooden head as accurately as possible. When cold the glass is held so firmly by the cement that it will break more easily than it can be pulled off.

Put the slide rest and tail stock of the lathe out of the way, take out the centre spur, and insert the wooden spindle in the mandrel, where it must fit tightly, so as not to work loose during the grinding process. Take a small emery wheel, or a piece of a broken wheel, in the right hand, set the lathe in motion, and hold the emery stone against the glass, grinding toward the edge at first, and working it into a convex shape. During the grinding, the glass should be kept wet with water, which may be conveniently done by touching it frequently with a wet sponge held in the left hand. It must not be allowed to get so hot as to melt the cement. After it has been worked into a smooth convex surface, stop the lathe and apply the concave gauge to it, which will show where the grinding is to be continued in order to produce the right curvature. The gauge test should be made frequently after the glass has nearly reached the intended size. Toward the end, the work must be conducted very carefully, as two or three seconds' pressure of the stone upon the glass in one position will grind it out of shape. It must fit the gauge so that on removing the centre from the lathe and holding it up before the eyes, no light can be seen passing between the glass and the gauge at any point. Replace the centre, and with very fine emery paper go over it some time to remove the deep scratches left by the coarse stone, testing frequently with the gauge. Follow this with a piece of very soft whetstone. This will leave the surface in good condition for the polishing process. Grinding a medium sized lens for a magnifying glass need not take over an hour, unless a needlessly thick piece of glass has been used. The hand soon acquires the correct way of moving

the stone around, so as to give the glass a smooth convex surface.

Now tie a piece of thin doeskin or other firm and thin woolen cloth, over the concave surface of the tin polisher, fastening it around the sides of the head. Slightly moisten the cloth, and put a small quantity of putty powder (oxide of tin) over it. Remove the wooden centre, with the glass, from the mandrel, and insert the polisher. Set the polisher revolving, and, using the wooden centre as a handle, press the glass into the concavity, which it will fit accurately. Keep up the application of moisture and putty powder frequently. Do not let the glass get hot enough to melt the cement, but remove it frequently to cool. Do not hold the glass in one position, but keep the hand moving across the plane of the polisher in every direction, taking care that in whatever position the hand is held the glass fits accurately into the polisher. If the doeskin gets worn through, replace it with another piece. When the polishing has proceeded so far that the surface of the glass appears brilliant, and no scratches remain visible to the naked eye, the dampening and application of putty powder should be stopped, and the polishing continued with what putty powder has worked into the cloth. The polishing will not take very much time if the grinding was properly finished with fine stone, as directed. It should be continued, however, until under a magnifying power of ten diameters the surface of the glass appears as bright and free from scratches as it does to the naked eye.

The lens can now be heated enough to melt the cement, when it can be slid from the wood. A little alcohol will remove the cement remaining upon it. If the whole process has been conducted according to directions, the lens should give a clear bright view of any object, as the words on this page, and, while looking, no sign of distortion should be visible on turning the glass around in the fingers.

In shaping and polishing the lenses, as in everything else, practice makes perfect. Care and attention to details are all that are needed, and after the process has become familiar it will be found easy, so that any one can make for himself a supply of lenses of various powers, and even make combinations that will do excellent service.

Middlebury, Vt., Jan. 11, 1879.

The Graver.

BY JOSHUA ROSE, M. E.

WHAT a wonderful field of usefulness that simple looking little tool, the graver, fills! It is used upon wrought iron, steel, copper, cast iron, brass and wood, as well as upon ivory, bone, tin, lead, and the softer metals, and it will cut

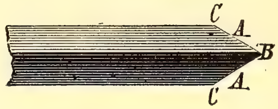

Fig. 1.

in almost any position in which its cutting edge can be brought to bear upon the work.

It consists of a square piece of steel, with the end face ground off at an angle, as shown in Fig. 1. The edges, A, A, extending on each side from B to C, as well as the point, B, being used to cut with. The machinist uses its point to cut work very true, holding it in the position shown

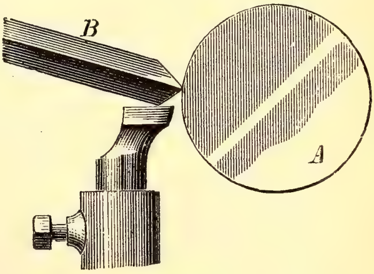

Fig. 2.

in Fig. 2, while to finish the work smooth he holds it as shown in Fig. 3. The brass finisher bevels off the face, as shown in Fig. 4, and the engraver turns it upside down as shown in Fig. 5, using the point, B, only. It will cut work that is parallel,

taper, having round corners, hollow sweeps, true curves, and moulding beads

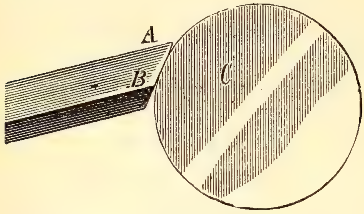

Fig. 3.

of any kind. It requires no forging, and will cut at a very quick speed. The end

Fig. 4.

face requires to be very true; hence when ground it is held as shown in Fig. 6. It is

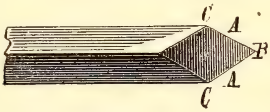

Fig. 5.

made very hard, and oilstoned for a polished finish, water being used when cutting wrought iron or steel.

When used with one point resting as a fulcrum upon the face of the lathe rest, that point should be pressed firmly to the rest to prevent the tool from slipping. Here it becomes necessary to caution the beginner against leaning the cutting edge too far over, as this is an error into which he is very liable to fall, and it invariably results in his losing control of the tool, and allowing it to rip into the work. Suppose, for example, that in Fig. 7, A is a

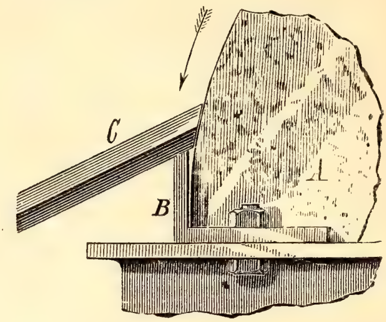

Fig. 6.

sectional view of a graver, B is the part receiving the pressure of the cut, and C is the lathe rest; the leverage of B is the distance between the vertical lines D and E, and the whole pressure of the cut at that leverage has to be resisted by a counteracting twisting pressure exerted by the hands upon the handle. The leverage of the cut as shown in Fig. 2 is, it will be

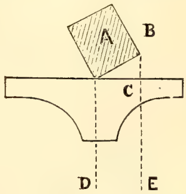

Fig. 7.

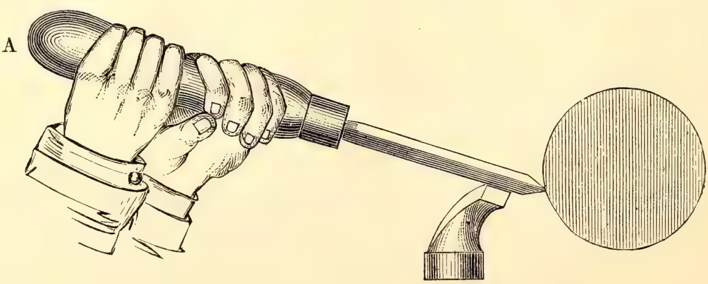

Fig. 8.

seen, much less, and therefore more under control.

The discussion of this point naturally brings us to another, namely, the shape of the handle. A file handle is often used for a graver, but it is highly unsuitable, for the graver requires, even for the smallest machine work, to be held with both hands, as shown in Fig. 8, the end of the handle, A, resting against the shoulder of the operator. The motion of the tool is given by twisting the handle from right to left, while at the same time the end, A, is moved laterally from left to right.

These facts show the wide range of usefulness which this tool covers; in skilful hands it may be made a substitute for almost every other turning tool, but it requires a little practice before the beginner learns the art of using it, and perhaps there is no test which so readily shows the skill of the turner as his power of making use of this little implement.

Engraving on Wood—III.

BY SARAH E. FULLER.

IN our second article, we said we would tell you how to engrave the flower piece, of which we explained the process of drawing. We will suppose you have your tools in good order, viz., well graded and nicely sharpened.

First lessons in engraving usually consist of exercises in making tints—at first straight line tints, and afterwards waved, curved and graduated. Then come lessons in outline work; afterwards pictures for which the work of the previous exercises has given the necessary training. At first these pictures should be simple, and, after some practice, those that are more difficult may be undertaken. But as you may be impatient to make a picture, we will tell you now how to cut the flowers and leaves in No. 2.

If you will examine very closely, you will discover a very fine white line on the inside of the edge line of the leaves, on each side of the veins, and around the flower petals. To cut this fine line, use No. 1 of the tint tools, and hold the block so that you can cut curves downwards. Use this same fine tool to cut all the darkest part of the tint, but be very cautious as your tool approaches the vein lines, so as not to cut through them. You will now find the use of the fine white outline, for as you approach the lines the little chip breaks off and drops out.

At the outer portion of this dark shade, it will be well to use your finest tool, but press it deeper into the wood than you did in the darkest part, and observe also to leave the black lines thinner than you did in the darkest part. For the next lightest tint, use tool No. 2. On the two upper leaves all the work will be done by these two tools, except a very small space on the upper left hand leaf, on its upper inner edge—there you will require your No. 3 or 4, which you will also need in the lightest tint on the large leaf.

In cutting any tints, you must use the tool that will make the gray you desire, for tints are really different shades of gray color, made up of black and white lines in alternation. Whenever you want to produce dark gray, you leave wide black lines, and cut out fine white ones. When you want it very light, the white lines are broad, and the black lines very "sharp," or "hair line."

For the lines on the stems, choose the tools that will make the different shades of gray—Nos. 1 and 2 will be the ones to use, with a higher number to make the broad white lines.

You will notice that the lines on the leaves are not entirely straight; they curve gently, and in portions are waved. The direction of the lines is generally chosen to indicate the form of the object represented.

After you have cut the leaves and stems, take a coarse tint tool, and cut across the ends of the tints on the petals, where the white spaces are, and outline with the fine tool close to the edges of the petals. Then choose the tool that will fit the tint, and hold the block so you can cut the curves downwards. Commence always at the top of any series of lines that make tints, so that each black line, as you cut it, will be above your tool, because you always need to see the line you are making.

You need to outline the stamens, but notice the little dark spot from which they

all seem to start. After you have cut the tints in the petals and the stamens, take out the white spaces, with tools best adapted. Do not try to take all out at once; several little gougings will be necessary, for here you need to cut out the wood somewhat deeper than you did when cutting the tints. Next cut away on the outside of the leaves and flowers all the blank wood, and your engraving is done. In digging out large spaces, you need to be careful that you do not injure the parts you have engraved.

The next thing will be to ink the cut, so that you can take an impression or "proof" of your work.

To make a dabber, take a large handful of loose wool, and tie it up in a stout piece of soft muslin; cover it with a piece of fine silk. Its shape should be circular, and large enough so that when tied it will make a convenient handle for the dabber. Wind this so that the ball part will be firm but yet elastic. Buckskin or kid may be used instead of silk, and the dabber may also be provided with a turned wooden handle.

A piece of thick glass, or small slab of fine stone, will afford a good surface for beating the ink fine. To take proofs you require the best quality of printer's ink; it should be that which is prepared purposely for taking proofs.

Put a small quantity on the slab, and, with the dabber, beat it very fine. After a few trials, you will be able to tell by the looks when it is beaten fine. When well beaten, proceed to ink the cut. Dab lightly, and let the dabber rest on the block a second or so, just long enough for the ink on the dabber to come off on the lines. Do not press the dabber down, or rub it over the cut, because in that way the ink will be smeared into the white spaces you have engraved. You want to ink the surface of the lines you have cut, and not get any ink into the spaces between.

After the block is properly inked, take a piece of India proof paper and lay it carefully on the surface of the cut. With an ivory paper cutter, rub over the whole surface of the picture, being careful, as far as possible, to rub in the direction the lines are cut. Hold the paper knife flat wise on the cut, and press gently, rubbing every part till the whole impression is made. If the paper is not too thick, you will soon see a faint impression through it. You must press very lightly on sharp and delicate lines, but may bear down on dark places, or those that are quite black. In this flower piece, you may use a moderate pressure on all parts except the petals. It is well to have your paper knife with one end in a blunt point, so that it can be used to press upon dark touches, as, for example, the centre spots of the flowers. But remember to keep the paper knife flat—do not use the edge, or you will bruise the lines you have cut. It is very easy to injure the delicate lines that make a wood engraving. A scratch or bruised spot will show in all the impressions made from the cut, so handle your cuts carefully. To keep your proofs, have a scrap book, and put into it proofs of all the cuts you make, in the order in which you engrave them; number them or date them, and you will thus have a record of your progress. Let each cut be made as carefully as if it was worth a great many dollars, and you will soon perceive that you make progress. But if you are careless, and do not take pains, you will never make a good engraver. The motto is applicable, "Make haste slowly."

If any of my young readers would like to ask any questions about anything we have gone over, I will answer them.

Learning to Use the Microscope—II.

HAVING provided objects for examination, the young microscopist is now ready to go to work. The light by which the examination is made may be either daylight or lamplight; good daylight is always to be preferred, but good lamplight is a great deal better than poor daylight, and it is not always that we can get good daylight. Where daylight is used, the light reflected from a white cloud or from a white wall is best; direct sunlight must never be used for ordinary work. At night any good lamp will do; what is known as the student lamp is undoubt-

edly the best. Considerable difference of opinion exists as to how the microscope should be placed in regard to the light, as, for example, whether it should be placed directly in front of the lamp or window, or to one side. To us it seems of little consequence, so long as the light falls full and fair upon the mirror, while the observer's eyes are completely shaded. A very simple arrangement of blackened paper or pasteboard will effect this, but if no such shade is at hand, the microscopist should sit with the lamp or window at his left hand, and his face directed to some comparatively dark part of the room.

The microscope being placed so that the light may fall on the mirror, the next step is to reflect a beam of light up through the microscope. The easiest way to do this is to place a transparent object on the stage, and turn the mirror until the beam of light falls squarely on it. Then look through the microscope, and if the field of view is not fully and equally illuminated, turn the mirror until by repeated trials this defect is removed. We are now ready to look at the object. It is supposed, of course, that the beginner has screwed on his *lowest* power; this is easily managed and will show a section of wood very well. Bring the objective down to within a quarter of an inch of the object, and while doing this do not look *through* the microscope, but watch the objective and the object from the outside. Then apply the eye to the eye-piece, and slowly move the body of the microscope, and with it, of course, the objective, upward, until the object is seen clearly and distinctly.

Before placing an object on the stage, see that the objective is raised at least half an inch above the stage, and when using high powers, never attempt to introduce a new slide without raising the objective; otherwise you run great risk of injuring both the object and the objective. This caution is peculiarly necessary, because in a little book that has been widely circulated directions the very reverse of these are given, and we are told to "1. Bring the objective down close to the stage. Do this before looking through the microscope. 2. Place on the stage the object to be examined." It would be impossible to suggest a better plan for breaking objectives and destroying slides.

These directions will enable the beginner to examine simple transparent objects, such as the eye, foot, tongue, etc., of a fly; sections of plants and of animal tissues, etc. Very many objects cannot be thus examined, however; the light cannot be made to pass *through* them, and they can be seen only by the light reflected from their surface. In this case it is almost always necessary to throw a very intense light upon the object, particularly if the object-glasses are not of the very best kind. To condense the light upon the object, a condensing lens is generally employed. The concave mirror, however, answers the same purpose, provided it can either be detached from the microscope and mounted on a separate stand, or raised above the stage, as is now arranged even in many of the cheaper forms of the compound instrument. To learn the use of the condensing lens or mirror, let the student arrange these in relation to the lamp so as to throw a bright spot of light on the object. In the case of the lens, the light passes through it, and is brought to a focus on the other side, just as a boy sets fire to an object by means of a burning glass. When the mirror is used, it is placed *beyond* the object, and the rays of light, after striking it, are reflected back again upon the object. In using either the mirror or the lens, it will be found necessary to place them at a proper distance from the lamp and from the object. If the lens be placed too near the lamp, the rays of the latter cannot be brought to a focus. It would be easy to give mathematical diagrams explaining this, but a few experiments will teach more than pages of writing.

— Certain manufacturers of a cheap microscope advertise it as follows: "It will show the tubular structure of hair; also the much-talked-of *trichina spiralis*, or pork-worm, which has caused so much excitement and so many deaths, thus furnishing an endless source of amusement and instruction combined"!!

Lessons in Magic—VI.

A Pretty Ring Trick.

FOR this trick, a handkerchief, a gold ring, a plate, a glass goblet, a thin light stick about eighteen inches long, and two assistants, are needed.

The goblet is placed on the plate, and each of the assistants requested to hold the latter by one hand. A ring is then borrowed, covered with the handkerchief, and given to one of the assistants to hold over the goblet.

He is then asked if he is certain that he has the ring, and on answering in the affirmative is told to drop it into the goblet, allowing the handkerchief to fall at the same time. With their disengaged hands, they are requested to take hold of the ends of the stick, which is placed horizontally under the plate. The performer begins the trick with the question,

"Are you sure the ring is in the goblet?"

"I think it is," the assistant will probably answer.

"Don't think about it, sir. Shake the goblet, and tell the audience whether you hear it rattle."

"Yes sir; quite distinctly," he answers.

The performer then approaches the goblet, and, taking hold of the handkerchief, bids the ring to "pass;" at the same moment, he raises the handkerchief, and the ring is seen revolving on the stick and the goblet is empty.

There is very little preparation required for this trick, the only thing necessary being to attach a ring to one end of a short thread, the other end of which is fastened to the centre of a handkerchief.

When the performer receives the ring, which he borrows, he pretends to cover it with the handkerchief, but instead of doing so, *palms* it, and gives the one that is attached to the handkerchief to the assistant to hold. The borrowed ring he slips on to the stick, and easily hides it with the hand that holds the stick. When it is laid under the plate, the handkerchief falls over it, and so prevents the audience from seeing it.

The one that is in the goblet is lifted out in the act of raising the handkerchief, care being taken that it does not strike against the sides of the glass.

When the trick is finished, the performer requests one of the assistants to help him with another trifling illusion. Having obtained his consent, he hands him the goblet used in the last trick, and asks,

"What is that article, sir?"

"A glass goblet."

"And what does it contain?"

"Nothing."

"Sir?"

"Nothing."

"SIR?"

"Nothing."

"SIR? Why it is full, sir; full of air. Do you know how that air may be displaced?"

"No, sir."

"By a very simple method. By merely filling the goblet to the brim."

And now commences

The Adventures of a Glass of Water.—The goblet is filled to the brim with water and placed on a table; the performer then covers it with a handkerchief, and taking it by the edge, offers it to the person who is assisting him. Just as he is about to take it, however, the performer shakes the handkerchief, and, lo! it is empty. He then asks the assistant if he can tell where it has gone, which, of course, he can not, unless he is a conjurer. The handkerchief is then spread out on the seat of a cane-bottomed chair, and to the astonishment of the audience, the performer lifts the goblet up from it as shown in the illustration (Fig. 7). The next moment, however, the handkerchief is thrown into the air, and is again empty. Finally it is spread out on his elbow, and once more, when Mr. Magician raises it, the form of the goblet is seen: the handkerchief is now removed, and the goblet is found to be still full of water.

To perform this trick, first get a wire ring made of the same circumference as the top of the goblet. This ring is laid to the centre of the handkerchief and stitched to it. When the goblet is to be covered, it is placed on the edge of the table at the back, and as the handkerchief is thrown over it, the performer takes hold of the bottom of it with his

left hand, and sets it on a shelf at the back of the table; at the same moment he takes hold of the ring with his right hand, and the handkerchief falling down, the

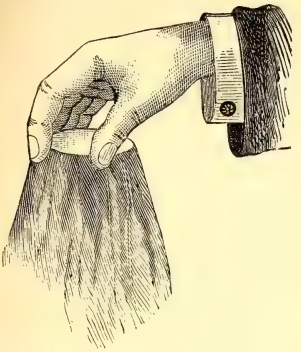

Fig. 7.

audience are not able to see whether the goblet is there or not, but from the shape will imagine that it is. When the handkerchief is shaken, the goblet seems to have disappeared, and when picked up by

Fig. 8.

the ring to have come again. In this way it can apparently be taken from any place.

To conclude the performance, the handkerchief is thrown over the left arm, which is held in the position shown in Fig. 8. The right hand is passed under the handkerchief, and takes from the inner left side pocket of the coat a goblet filled with water and covered with a piece of bladder. The bladder is moistened about the edges, and pressed against the sides of the glass, where it will tightly adhere. As the goblet is brought out from beneath the handkerchief by one hand, the fingers of the other hand clip (through the handkerchief) the edges of the bladder, and pull it off. The audience, this time, seeing the goblet filled with water, imagine that it was under the handkerchief each time that the shape of it was seen.

Editorial Notes.

Autographs.

WE have just received a small lot of very neat autograph albums, the regular price of which is 15 cents. We will send one of these albums, and also a copy of the "Amateur's Handbook," (price 15 cents), to any of our subscribers that will send us a new subscriber and fifty cents.

Postage Stamps.

SINCE the postal currency has been withdrawn from circulation, it is difficult to send fractions of a dollar by mail. We therefore announced that we would accept postage stamps at their full value for subscriptions. Some of our readers, however, seem to think that we *prefer* postage stamps; this is not the case, as we are in receipt of a much greater number of postage stamps than we can use, and consequently we have to dispose of them at a sacrifice. Hereafter we shall accept postage stamps only in amounts less than one dollar, and we would further say that stamps of large denominations are of no use to us; even three-cent stamps are a drug, but one and two-cent stamps we can always use. Canadian postage stamps are of no use to us. British postage stamps we receive at their full value.

The Heavens for April.

BY BERLIN H. WRIGHT.

PLANETS.—MERCURY will be invisible throughout the month.

VENUS will perceptibly increase in brilliancy this month, her apparent diameter increasing from 12″ to 13″.6—four times her increase in March. She will be 2¼° south of the Moon on the 24th, and will pass south of and very close to the Pleiades on the 15th. She is moving eastward past the stars, and until the 20th will be in the constellation Aries, and after that date in Taurus, being exactly midway between Betelguese and Auriga May 8. She sets as follows:

April 15—9h. 15m. evening.
" 25—9h. 38m. "
May 10—10h. 6m. "

The gibbocity of her phase will decrease as she recedes from the sun, and approaches her greatest eastern elongation, at which time one-half of her illuminated surface will be visible.

MARS will be about 3° south of the Moon on the 15th. He will be in the constellation Capricornus until the 24th, and after that date in Aquarius, rising as follows:

April 15—2h. 57m. morning.
" 20—2h. 47m. "
" 30—2h. 28m. "
May 10—2h. 7m. "

Mars and Jupiter will be less than one degree apart May 9, in the morning, Mars being the most southern.

JUPITER will be 4° south of the Moon on the 16th. He rises as follows:

April 15—3h. 31m. morning.
" 20—3h. 13m. "
" 30—2h. 38m. "
May 10—2h. 2m. "

SATELLITES OF JUPITER.—Satellite I completes a transit April 3, 4h. 58m. morn., and begins one, April 10, 4h. 39m. morn.; disappears in Jupiter's shadow April 25, 4h. 38m. morn., and reappears from behind the planet May 4, 4h. 32m. morn.

Satellite II disappears in Jupiter's shadow April 29, 3h. 45m. morning, and begins a transit across the planet's disc May 8, 3h. 3m. morning.

Satellite III reappears from behind the planet April 14, 2h. 29m. morning, and disappears in Jupiter's shadow April 28, 4h. 42m. morn.; reappears from an eclipse April 21, 4h. 14m. morn., and completes a transit May 2, 3h. 25m. morn.

All eclipses of Jupiter's Satellites must take place to the west of the planet at present, as his shadow is now thrown westward. At the time of the eclipse of Satellite II, above referred to, the Satellites will occupy the following positions with respect to Jupiter:

I, east, three times the apparent diameter of Jupiter.

II, west, half as far as I is east.

III, east, one and a half times as far as I.

IV, east, nearly five times as far as I, or at greatest distance. Hence, after the eclipse of II the three visible Satellites will be east of Jupiter. (For an inverting eye-piece reverse these directions).

SATURN is not favorably situated, rising as follows:

April 10—5h. 14m. morning.
" 20—4h. 37m. "
" 30—4h. 0m. "
May 10—3h. 23m. "

URANUS passes the meridian as follows:

April 15—8h. 35m. evening.
" 25—7h. 55m. "
May 10—6h. 56m. "

NEPTUNE will be in conjunction with the Sun April 30, and will be invisible for a long time before and after that date.

METEORS.—The following are the meteoric epochs for April: April 10—14; radiant in Virgo, April 20; period 27 years, *probably,* which would bring it in 1884, but as there is considerable uncertainty about the period, watch should be kept in the vicinity of its radiant—the Northern Crown: April 25, radiant near the head of Perseus, and April 30. Prof. Daniel Kirkwood, LL. D., finds that the orbit of the April 20 meteors and the first comet of 1861 are identical.

EPHEMERIDES OF THE PRINCIPAL STARS AND CLUSTERS FOR APRIL 20, 1879.

	H.	*M.*
Alpha Andromadae (Alpheratz)	invisible.	
Beta Persei (Algol) sets	10	13 even.
Eta Tauri (Pleiades) sets	9	13 "
Alpha Tauri (Aldebaran) sets	9	31 "
Alpha Aurigae (Capella) sets	1	24 morn.
Beta Orionis (Rigel) sets	8	44 even.
Alpha Orionis (Betelguese) sets	10	18 "
Alpha Canis Majoris (Sirius) sets	9	45 "
Alpha Canis Minoris (Procyon) sets	11	56 "
Alpha Leonis (Regulus) in meridian	8	6 "
Alpha Virginis (Spica) rises	6	0 "
Alpha Bootes (Arcturus) in merid.	0	18 morn.
Alpha Lyrae (Vega) rises	7	43 even.
Alpha Aquilla (Altair) rises	11	19 "
Alpha Cygni (Deneb) rises	8	46 "
Alpha Pisces Australis (Fomnalhaut) rises	4	58 morn.
Alpha Scorpionis (Antares) rises	10	6 even.

VARIABLE STARS.—MIRA CETI is now invisible to the eye—7.0 magnitude, and slowly fading.

Beta PERSEI (Algol).—The following are the *visible* minima for April:

April 6—11h. 3m. evening.
" 9—7h. 52m. evening.

April 17—10h. 20m. evening.
" 20—7h. 10m. evening.

S Cancri.—*Minimum*—April 19, 10h. 57m. eve. This star has a period of 9.48 days, and changes from the 8th to 10.5th mag. To enable the amateur to find it we will give its place: Right ascension, 8h. 36m.; declination, 19° 30′ N.

Delta Libra.—Period 2d, 7h. 51.0m.; R. A., 14h. 53m.; dec., 7° 58′ S. Near the right foot of the Virgin. Changes from 4.5 to 6 magnitude. *Minima:*

April 3—5h. 44m. morning.
" 7—9h. 26m. evening.
" 10—5h. 17m. morning.
" 15—9h. 0m. evening.
" 17—4h. 51m. morning.
" 21—8h. 33m. evening.
" 24—4h. 25m. morning.
" 28—8h. 7m. evening.

LONG PERIOD VARIABLES.

Use of Sandpaper.

It would seem as if sandpapering were one of the easiest and simplest matters, and yet there are few things connected with this art that are so little understood. The ordinary way with the novice is to tear off a piece of sandpaper, hold it with his fingers, and rub the wood with it. This method is very likely to lead to bad results. If it is a piece of open work that needs smoothing, the paper takes off too much wood at the edges, and rounds them off. Or, if it is a flat piece of wood, the fingers bear on harder in some places than others, and make the surface uneven.

Now, there are two ways to sandpaper nicely. If the piece of work is small, fasten a whole sheet of sandpaper to your bench or a flat, smooth board, and rub the wood over it. This is the best method for all small articles. For general purposes, however, it is best to make a sand-board, which is done in this way: Cut two pieces of smooth pine, three-eighths of an inch thick, three inches wide and four long; through one of them put three slender screws in a line and one and one-half inches apart, long enough when the heads are driven in flush with the wood to have the points project about one-fourth inch on the other side. File these points sharp, and make corresponding holes in the other block. Now cut a piece of sandpaper four inches wide and seven and one-half long, and lay one end upon the screw points, pressing them through the paper. Then stretch the paper tightly around the block, and fasten the other end upon the points. Lay upon this the other block, and fasten the two together with a screw at each end. A pair of common screw-eyes that are used for hanging picture frames will be useful for this purpose. It would be well to have two sets of these blocks made to hold coarse and fine sandpaper. Now lay the work upon the bench, hold it with one hand, and rub with the sand-board, carefully and briskly, and with a circular motion. If the wood is at all rough, begin with No. 1 sandpaper, and finish with No. 00. Before using the paper on any fine work, examine it carefully, and pick out any large pieces of sand which might score the wood.

If the amateur is fortunate enough to possess a turning lathe, he will find that the following contrivance will save him a great deal of labor: Make (or have them made by some turner) several cylinders of wood, four inches long and three and one-half in diameter. Stretch around one of these a half sheet of sandpaper, and glue the two ends to the wood. Set this in the lathe, revolve rapidly, and it will smooth the wood very quickly. The writer uses half a dozen of these cylinders, with a different number of sandpaper on each.—*Arthur Hope.*

Cork Stamps.

A great many business houses make use of rubber stamps, which are manufactured in large quantities and sold at a good profit, the business being comparatively new. The stamps are made by setting up the desired words in common type, precisely as for printing. A matrix is then obtained by covering the face of the type with moistened plaster of paris, which is allowed to remain until "set," after which this reverse impression is filled with the prepared rubber. When the rubber filling is taken from the plaster mold, it is a perfect fac simile of the type from which the cast was taken, and after being mounted on a convenient handle, is used for printing as a hand-stamp.

A good substitute may be made in cork by cutting the letters with a sharp penknife on the end of a smooth bottle cork, of sufficient size to hold the words intended to be printed—of course cutting the letters and spelling the words backwards, that the impression may appear properly. Our young readers will find this an instructive amusement, and many short words and sentences, such as "PAID," "ACCEPTED," "ANSWERED," "RECEIVED PAYMENT," "P. O. BOX," etc., would prove acceptable to a father or a brother, for use on the office desk.

The same ink is used as for rubber stamps, and may be procured at most stationers. One drop on a piece of flannel is sufficient, and will remain moist a long time. The cover of a wooden pill-box makes a good receptacle for the ink pad, and with this the outfit is complete.

To Straighten Warped Woods.

Of all the trials and vexations that beset the beginner, there are none more annoying than the tendency of wood to warp. He sends to his dealer for a small assortment of fine woods, and expects to receive them perfectly true and flat. Perhaps the woods are flat when they leave the dealer, but in transit they are very likely to twist out of shape, reaching their destination badly warped. The expressman may not be aware of the subtile nature of these woods, and in not a very gentle manner lays the package on a damp, cold floor. The dry wood sucks in the moisture on one side, swells and curls. It should not be a difficult matter to cure this. If the wood is in a large piece, the convex or hollow side should be steamed or moistened a little, and then laid upon a dry floor, holding it down with a smooth, flat board, upon which weights are placed. When quite dry, it will be found to have regained its original shape. If the wood is in small pieces, it can be easily straightened by gently steaming the convexed side over a tea-kettle, and then holding the other side towards the heat until it becomes straight, when it can be left in a press or under weights for a few hours. Almost any warped woods will yield under this treatment.—*Leffels' News.*

BOOK NOTICES.

Rhymes of Science—Wise and Otherwise: Containing Poems by O. W. Holmes, Bret Harte, R. W. Raymond, J. W. McQ. Rankine, and others. New York: Industrial Publication Company.

In addition to several familiar pieces by well-known authors, such as the "De Sauty" of Holmes, the "Pliocene Skull," and the "Society upon the Stanislaus," by Bret Harte, this little volume contains a large number of fugitive pieces which seem never to have found a place except in the pages of some periodical. Some of these are very good—as witness the new version of "I'd be a Butterfly," and the "Tail of Long Ago," by some unknown author.

The book cannot fail to afford a good deal of amusement. Scientific men will appreciate it for the burlesque which it gives of many points in science, and others will relish it for its fun alone.

Practical Hints.

Imitation Mahogany.—Brush over the wood with common ink; when that is dry, brush it over with dragon's blood mixed with methylated spirit in the proportion of one ounce dragon's blood to one-half pint of the methylated spirit. When that is dry, varnish with spirit varnish.

Indestructible Ink.—The Boston *Journal of Chemistry* gives the following directions for preparing an indestructible writing ink: An ink that cannot be erased with acids is obtained by the following recipe: To good gall ink add a strong solution of fine soluble Prussian blue in distilled water. This addition makes the ink, which was previously proof against alkalies, equally proof against acids, and forms a writing fluid which cannot be erased without destroying the paper. The ink writes greenish blue, but afterwards turns black.

Tanning Sheepskins with the Wool On.—Sheepskins and the hides of some dogs make excellent mats, rugs, etc. The following process has been found to succeed very well: Tack the skin upon a board with the flesh side out, and then scrape with a blunt knife; next rub it over hard with pulverized chalk, until it will absorb no more. Then take the skin off from the board and cover it with pulverized alum; double half-way over, with the flesh side in contact; then roll tight together and keep dry for three days, after which unfold and stretch it again on a board or floor, and dry in the air, and it will be ready for use.

How to Kill Entomological Specimens.—A correspondent says the method of killing entomological specimens, by putting them in a glass cylinder closed at one end, and then inserting a wad of tow saturated with ether on closing the other end of the cylinder, is very good; but when putting the insect, especially butterflies, in the tube, it flutters its wings, and so loosens some of the colors. A better way is to put a small bit of chloroform on the insect's head as soon as it is caught, and the effect is that it instantaneously dies, not even a relaxation of the muscles being perceptible.

Liquid Slating for Blackboards.—Alcohol, (95 per cent). 4 pints; shellac, 8 ounces; lampblack, 12 drachms; ultramarine blue, 20 drachms; powdered rotten stone, 4 ounces; powdered pumice stone, 6 ounces. First dissolve the shellac in the alcohol, then add the other ingredients, finely powdered, and shake well. To apply the slating, have the surface of the board smooth and perfectly free from grease. Shake well the bottle containing the preparation, pour out a small quantity only on a dish, and apply it with a new flat varnish brush as rapidly as possible. Keep the bottle well corked, and shake it up every time before pouring out the liquid.

Depositing Brass by Electricity.—Herr Hess, in the *Metallarbeiter*, gives the following directions for this process: The first step is to thoroughly cleanse the articles, either by means of emery, or by laying them overnight in a weak bath of sulphuric acid. They are then washed off with water, a weak soda solution, and then immersed as the cathode of a bath consisting of 2½ parts of sulphate of copper, 20 parts sulphate of zinc, and 45 parts cyanide of potassium, in 300 parts of water. The anode should be two plates of zinc and copper of equal size. The color of the resulting brass coating may be modified by varying the depth of immersion of one or the other of the plates. The galvanic current should be a strong one, and the liberation of hydrogen bubbles on the object to be brassed should be plentiful. It is important, however, to note that the objects should be first coppered to insure a strong attachment of the brass coating.

Stimulating Progress among Young Mechanics.—Honorable competition in actual work is a great incitement to progress. This, we think, is well applied by an English society of turners. The subjects of competition were: turning in ivory, pottery, stone and jet; and steel, brass and gold for horological purposes. The competition in ivory included vegetable ivory. The qualities considered in awarding the prizes were: Beauty of design, symmetry of shape, utility, and general excellence of workmanship; exact copying, so that two objects produced should be fac similes in every part, or exact measures of capacity: fitness of the work or design for the purpose proposed; ability to turn, whether circular or oval; and novelty in application of turning or in design. Carving was admissable, but it was to be subsidiary to the turning. The candidate was to make his own selection from the above conditions; but the one who best fulfilled the largest number, including the most important qualities, was preferred. The work to be all hand-turning, produced in the lathe, without special rest or tool apparatus, and the carving to be the work of the exhibitor.

Fitting Glass Stoppers.—Very few stoppers fit properly the bottles for which they are intended. The stoppers and bottles are ground with copper cones, fed with sand and made to revolve rapidly in a lathe, and the common stock are not specially fitted. To fit a stopper to a bottle that has not been ground, use emery or coarse sand kept constantly wet with water, and replaced with fresh as fast as it is reduced to powder. When all the surface has become equally rough, it is considered a sign that the glass has been ground to the proper shape, as until that time the projecting parts only show traces of erosion. This is the longest and hardest part of the work, as after that the glass simply needs finishing and polishing. For that purpose emery only can be used, owing to the fact that the material can be obtained of any degree of fineness, in this respect differing from sand. Otherwise the operation is the same as before, the emery being always kept moistened, and replaced when worn out. The grinding is continued until both the neck of the bottle and the stopper acquire a uniform finish, of a moderate degree of smoothness, and until the stopper fits so accurately that no shake can be felt in it, even though it be not twisted in tightly.

Uranine.—This is the most recently discovered, and perhaps the most remarkable, of all the coal tar or aniline group of coloring substances, now so extensively used for the adornment of the finest fabrics. Uranine is said, by chemists, to be the most highly fluorescent body known to science. Its coloring power is astonishing; a single grain will impart a marked color to nearly five hundred gallons of water.

A most interesting experiment, which anybody may try, consists in sprinkling a few atoms of uranine upon the surface of water in a glass tumbler. Each atom immediately sends down through the water what appears to be a bright green rootlet, and the tumbler soon looks as if it were crowded full of beautiful plants. The rootlets now begin to enlarge, spread and combine, until we have a mass of soft green-colored liquid. Viewed by transmitted light, the color changes to a bright golden or amber hue; while a combination of green and gold will be realized, according to the position in which the glass is held. For day or evening experiment, nothing can be prettier than these trials of uranine, which are especially entertaining for the young folks. We are indebted for examples of the color to the editors of the *Scientific American*, who are sending out specimens, free of charge, to all their readers.

EXCHANGES.

Yearly subscribers to the Young Scientist have the privilege of inserting three exchanges (or one exchange three times) during the year. This privilege is strictly confined to *exchanges; buying and selling* must be carried on in the advertising columns, where the charge is 30 cents per line. Each exchange is limited to thirty words, making about four lines, and in order to receive attention must be written on a slip of paper by itself. We file all letters received, and have no time for copying out exchanges and queries.

As we desire to make the journal of the utmost value to *all*, and not merely to serve the interests of individuals, we shall strictly adhere to these rules, which are certainly liberal, giving as they do advertising to the value of $3.60 free to each subscriber.

Wanted, a collection of Southern woods, for a collection of New Hampshire woods; will exchange for rough pieces. W. P. Adams, Pittsfield, N. H.

For exchange, a guitar, patent head, nearly new, cost with strings $14—splendid instrument, in good order; state what you have to exchange. W. Z. Allen, Monrovia, Ind.

A No. 1 self-inking Official press, costing $10, and $13 worth of type and fixtures, to exchange for a combined bracket saw and lathe, or offers. C. A. Bacon, Elba, Lapeer County, Mich.

To exchange, Bourne's "Treatise on the Steam Engine," cost $5, for chemical apparatus and chemicals of the same value. E. T. Birdsall, 39 East 22d street, New York.

Wanted, 350 or 400 different kinds of foreign stamps; state what is wanted in exchange. John S. Briggs, Newark, N. Y.

Wanted, January and March (1878) Nos. of Young Scientist in exchange for the "Mineralogist Companion." Walter Brockstedt, 2118 Carondelet Avenue, St. Louis, Mo.

Printing press, cost $35, and several fonts of type, in exchange for anything pertaining to science, literature or art. E. S. Dayton, Basking Ridge, N. J.

To exchange, one telegraphic key and sounder, in good shape; also a new scroll saw; state offers. John Duff, Jr., Pontiac, Ill.

Two Bunsen batteries to exchange for engraver's tools, or Vols. 1 and 2 of Scott's "Coin Journal," or old U. S. coins. Clark Horn, Jr., Box 582, Scranton, Pa.

An oscillating steam engine, 1-inch bore, 2-inch stroke, for a Queen's Household microscope, or offers. L. Kent, Santa Anna, Los Angeles Co., Cal.

Wanted, in exchange for valuable books (of which lists will be sent on application), Packard's "Guide to the Study of Insects," edition of 1876. C. H. L., 57 North 1st street, Edgefield, Tenn.

To exchange, cocoons of Attacus Luna, Cecropia and Polyphemus, for specimens of entomology or geology. Geo. A. Lippincott, Box 50, Watsontown, Northumberland Co., Pa.

A new stationary steam engine of ½-horse power, worth $30, in exchange for a good watch, or almost anything; mention offers. H. Mackenzie, Jr., Petroila, Ontario, Canada.

To exchange, complete set drawing instruments, cost $3; state offers. J. Mueller, 2453 Kosciusko street, St. Louis, Mo.

In exchange for books, a Novelty printing press in excellent condition, prints a form 6½x10½ ins.; cost $32, ink roller cost 75c., and $1.50 worth blue ink. J. A. Osborn, Scientist, Mahmal, Cambridgeport, Mass.

To exchange, a Novelty printing press, type and accessories, for a microscope with accessories, or minerals, or offers. T. W. Patterson, Warsaw, N. Y.

Will exchange one or more of my new extension step fruit ladders, the "Climax," price $2.50, for merchandise. H. E. Phelps, Marshall, Mich.

Wanted, an achromatic photo camera, a good shotgun, or scientific books or apparatus, in exchange for a fine scroll saw in good condition. A. B. Porter, 501 N. Tenn St., Indianapolis, Ind.

"The History of Our Country," by Benson J. Lossing, cost $15; also other books to exchange for scientific and practical books and apparatus. H. M. Rauschkolb, 246 Delord St., New Orleans, La.

Telegraphic key and sounder, finely wrought on proper base, cost $8; will exchange for good revolver. S. G. Reese, Box 133, Elizabethtown, Lanc. Co., Pa.

To exchange, one set of Lily carving tools of three pieces; state what is offered in exchange. B. M. Rockwood, Franklin, Mass.

Wanted, a first-class work on entomology, with colored plates, for Stanley's Travels, calf bound, nearly new; also other books and minerals to exchange. H. Salisbury, Box 399, Whitewater, Wis.

Wanted, a coachmaker's vice, opening 8 or 9 in., in good order, or a lot of thumb screws, in exchange for an E-flat cornet worth $15, or violin worth $12. B. H. Smith, New York Mills, Oneida County, N. Y.

Wanted, a Seltz's boys' theatre; state what is wanted in exchange, and give full particulars of the style of theatre. H. C. Spaulding, 7 Princeton street, Boston, Mass.

Kane's Arctic Explorations, for a small printing press with type and ink. H. B. Taylor, Tehuacana, Limestone Co., Texas.

A game of parlor billiards, cost $4, will be given in exchange for something of equal value. J. H. White, Canajoharie, N. Y.

Back numbers of "Youth's Companion," for the years 1877 and 1878, in good condition, to exchange for chemicals, chemical apparatus, or offers. F. Willis, 3 Myrtle street, Boston, Mass.

THE

YOUNG SCIENTIST.

Published Monthly at 50 cents per year.

Postage free to all parts of the United States and Canada, except New York City, where the law requires 12 cents extra postage, making the subscription in New York City 62 cents.

Postage stamps taken at full value, but only for amounts less than $1.00. One and Two-cent stamps preferred.

TO ADVERTISERS.

The Young Scientist has been received with so much favor that its circulation is already greater than that of any other monthly Scientific or Mechanical journal published in the city of New York. It goes into the best families, and has their confidence. No clap-trap advertisements, or advertisements of patent medicines received at any price.

Advertising Rates—30 cents per line, agate measure.

All Communications should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 2852. 176 Broadway, New York.

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

INDUSTRIAL PUBLICAT[ION]

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, MAY, 1879. No. 5.

Scroll Sawing—I.

BY F. T. HODGSON.

OF course, every boy, and a great many girls that we know, would like to own a good scroll saw; and this desire is a laudable one, and we know of no reason why it should not be gratified, for a knowledge of the use of the saw and its employment has a tendency to awaken and develop any artistic talent that might otherwise have remained dormant in the youthful operator. It is also a source of amusement, affording as it does a pleasant pastime for all who take an interest in the work; it can at the same time be made profitable, as many of the beautiful articles that can be produced sell readily at remunerative prices.

It is true that many boys and girls cannot afford to buy the more expensive saws; but they should not be discouraged on that account, for if they are unable to procure a foot machine, they should try and get a "hand" or frame saw, such as we show in Fig. 1, which, if made of beech or other native wood, can be obtained for about seventy-five cents.

In using this saw, at first, it will be found very difficult to control, but by a little perseverance, it will become tractable enough, and when once the mastery is obtained, you will have arrived at a point of excellence that is scarcely ever reached by the person who has never used a hand sawing-frame.

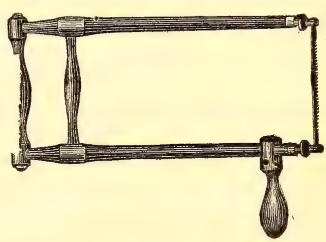

Fig. 1.

There are many kinds of frames for saws, each kind possessing some special quality of its own, but the simplest we ever saw was made with a single piece of ash, about ten inches long, and probably three-eighths of an inch in diameter; a slot, or groove, was cut in each end with a fine saw—it was then bent over like a bow,

and the fret saw, which had previously been heated at the ends and turned over, was inserted in the grooves, and the tension on the bow kept the saw taut. This little device did excellent work, and was easily adjusted, as the saw could be instantly removed by simply bending the bow.

Fig. 2 will convey an idea as to how the saw was formed. It will be seen that the fret saw forms the string, as it were, of an

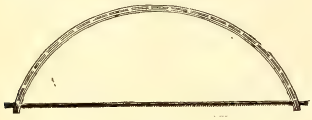

Fig. 2.

ordinary bow. A little ingenuity displayed in this direction, and the expenditure of a few cents for saws, will enable any boy to make a saw frame like the one just described, and when once in possession of a saw capable of doing good work, it will not be saying much for the owner's intelligence and industry, if he does not soon make it earn money enough to purchase a good foot-power machine.

Fig. 3 shows another style of a *home-made* saw frame, which can be constructed at small cost by any one who can use carpenter's tools. The jaws, *o o*, are made of

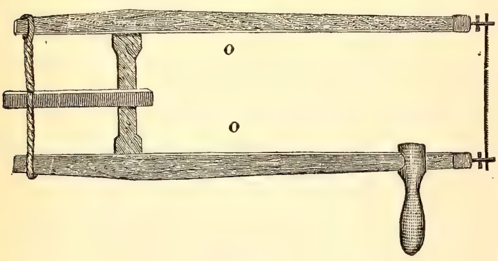

Fig. 3.

dry, straight-grained beech or maple, and are about twenty inches in length, and one inch square. They require to be made tapering toward the ends, as shown in the drawing, the ends near the saw being finished to about half an inch square, and the other end finishing up to about three-quarters of an inch square. At the point where the stretcher is mortised into the jaws, the latter should be left the full size of the wood, for it is there where the greatest strain exists, and the jaws will be weakened somewhat by the mortises being made in them. The jaws should be rounded off or chamfered a little to the outside of the frame from end to end, as it makes the frame look so much neater and workmanlike.

The next thing will be to make the stretcher, which should be about nine inches long and one inch square. A piece of straight-grained pine is good enough for this purpose, as it has not much strain to resist. Cut tenons on each end, as shown in Fig. 4, about half an inch long, and three-eighths of an inch thick. Cut

Fig. 4.

out the sides with a spokeshave, same as shown, then mortise the jaws, to receive the tenons on the stretcher, about five inches from the tail ends, and see that the tenons fit nice and snug, but not too tight. It is very important that this part of the work should be well done, for if there is any lost motion crosswise of the saw, it will be very difficult to make it cut straight.

Notch the jaws at the tail ends on the outside edges, to receive a cord, as shown at *s*, in Fig. 3. The use of the cord is easily understood; the slat of wood that runs through it is about three-quarters of an inch wide, and about one-quarter of an inch thick. In tightening up the cord, the slat will require to be pushed up until there is room enough for it to pass the stretcher, when the saw can be made taut, after which the slat can be slipped down until it assumes the position shown in Fig. 3.

The next thing will be to make a neat handle, which can be done as follows: Take a piece of good tough wood, about one and a quarter inches by one inch, and six inches long; bore a straight hole, half an inch in diameter near one end and through the flat side; fit it to one of the

jaws, as shown, then work it off something like the shape shown in Fig. 5. This handle may be fastened to the jaw by a small screw or a little wedge or key, which

Fig. 5.

may fit into a slot left in the handle, as shown.

On the saw ends of the jaws it is desirable to have ferrules made of tin, copper, or brass, nicely fitted on, as they prevent them from splitting when the clamps are screwed in. These ferrules, or thimbles, can be obtained in any hardware store; if not, a couple of common thimbles, filed down and nicely fitted on, make excellent substitutes.

For a clamp to hold the saw, we know of nothing in the market so cheap and efficient as the one shown in Fig. 6, which can be obtained from most hardware stores for about twenty or twenty-five cents a pair. The shank on each one is

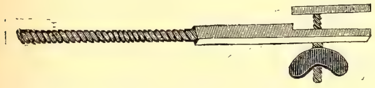

Fig. 6.

from one and three-quarters to two inches in length, and has a thread cut on one end for about an inch in length, the other end having a thumb-nut and screw, as shown. Great care must be taken to get these clamps in straight and true, and to prevent the ends of the jaws from splitting.

When the clamps are in place, the handle on, the saw made fast, and the cord tightened up, the work is nearly completed; all that is then to be done is to sandpaper the whole work, and give it two or three coats of raw linseed oil, rub in, then wipe off surplus oil with a clean cloth, and you will have a saw complete in every particular, for the small sum of forty cents. You will also have received a lesson in practical mechanics that is worth more to any boy than the value of a dozen saw frames,

Drawing Lessons—II.

BY JOHN CLARK CENTER.

NOW that you understand the difference between perpendicular, horizontal, and oblique lines, let us turn our attention to angles and their peculiar relations to some standard of measurement.

Right angles are easily recognized when we have to deal with perpendicular and horizontal lines; but if they should be

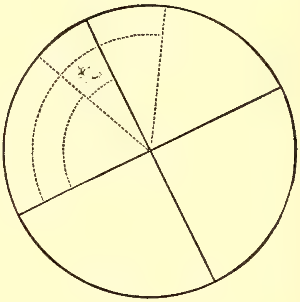

Fig. 1.

placed in an oblique position their character is not so obvious. A right angle is contained between any two lines proceeding from the centre of a circle, which include one-fourth part of the circumference or ninety degrees. If even a single degree less than this it becomes an acute angle, and if larger than ninety degrees it is an obtuse angle. To impress on the mind the

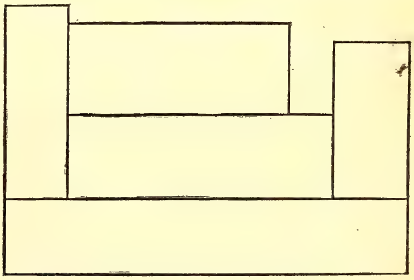

Fig. 2.

appearances of these angles in different positions, the student should devote some time to drawing them and studying their relations.

A square is a figure circumscribed by

four lines of equal length, united to each other at right angles.

A parallelogram is composed of four straight lines, the opposite sides being parallel and equal; but the adjacent sides may be unequal. Place several of these in conjunction and study their positions, etc. (Fig. 2).

A superficies is a surface of any form.

A cube is a solid body having six equal square sides, and all its angles right angles. A model of one should be procured by the student; as the laws of perspective can be simplified by observing the different angles produced by every change of its position in relation to the eye.

The cube being placed before the eye will illustrate this perfectly, as the top and sides, although square, do not appear to be so, and the purpose of drawing is to represent objects as they are seen. In the cube (Fig. 3), the top, which in nature is square, is represented by a figure narrower than it is long, and with two acute and two obtuse angles.

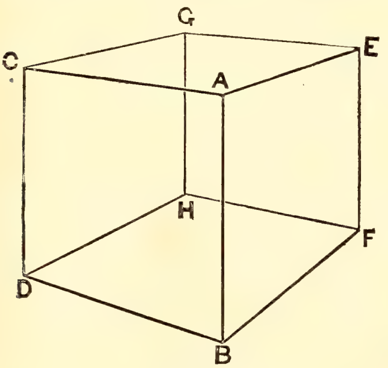

Fig. 3.

Lines converge when they are inclined toward each other, and if extended in this direction they will meet at some point. To prove the form that a square assumes, place the image of one in a perpendicular position with one end retreating from the eye—the end removed will appear shorter, and in the horizontal will appear to converge to some point.

Let us construct a cube with these ideas distinctly before us, and without the actual knowledge of perspective we can train the hand and the eye to do much.

Fix the perpendicular A B, of any length, and as the eye is to look down on the cube, draw C A, foreshortened, or less than A B, which is the only line seen of its real length. Next draw C D shorter than A B, (but longer than C A), because it is more distant; again join D B. Here we have the square A, B, D, C in perspective. Now determine the slope of A E, which being more foreshortened than C A, will slope more and be shorter. Again, E F being more distant than C D, will also be shorter. Join B F. Fix on the point G, so that G E shall be shorter than C A, and G C shorter than A E, being more distant: then the line G H being most distant, will be the shortest perpendicular, and joined with D and F, we will have the figure complete.

We will now observe that the figure A, C, G, E, the top of the cube, is narrower than B, D, H, F the base, because it is more on a level with the eye, and we see less of its natural form. Thus we have now learned that although lines are of equal length in nature, in drawing they should be made smaller according to their distance. Angles are also modified and obey a similar law. This important exercise should be practiced by an indefinite number of examples, changing the position of the cube in relation to the eye; for the diagrams so constructed are the bases on which we fill in the varied forms from nature.

In the construction of a diagram for practical purposes, we must be able to divide and subdivide its sides into proportionate parts. Take the following example (Fig. 4). In drawing a building we construct the side A, B, D, C, then A, B, F, E. Now if we want to divide either of these sides into any given number of equal parts, divide A B, and C, D, into the given number, join the corresponding points, and draw a diagonal from A to D. The points of intersection will give the positions for the perpendicular and proportionate divisions. In these may be described arches or windows in perspective.

By a well grounded practice in exercises which almost any object may suggest, the

student will have laid a groundwork for understanding the more complicated lessons that will treat on perspective, which when presented to the unprepared mind are an obstacle that puzzles and confuses, and is very little understood by many an

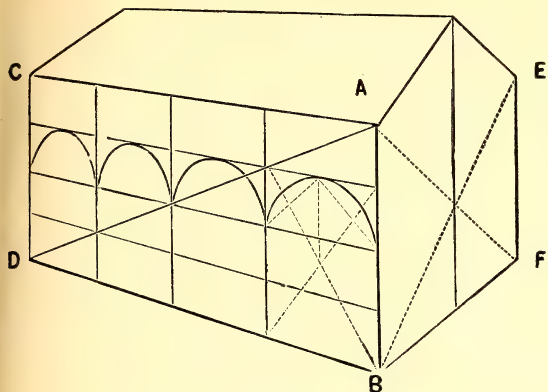

Fig. 4.

accomplished artist, who depends more on manipulation and natural instinct than upon complicated methods.

It will be found that by placing a number of books on the table and studying

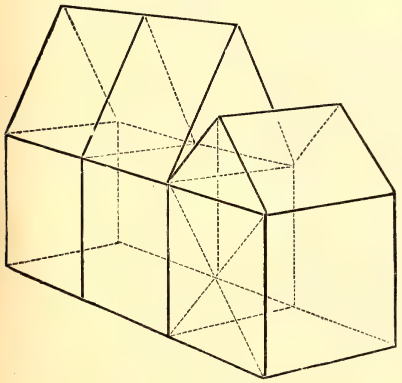

Fig. 5.

their relative positions, good examples can be easily had; other objects may be added of a more complicated form.

The examples shown in Fig. 5 are suggestive of arrangements and changes in position, of which it is so important to have experimental knowledge. All this must be learned by practice and industry, from which alone comes skill.

Home-made Hanging Basket.

BY A. W. ROBERTS.

THE variety of materials which may be applied to the construction and ornamentation of hanging baskets is almost infinite. Amongst others, shells and corals, and "sea mosses," afford material for constructing unique and pretty baskets, an example of which is shown in the engraving (Fig. 3). The foundation consists of a common earthen flower-pot which was first warmed in an oven, and then coated thickly on the outside with asphalt cement.

Around the rim of the pot are fastened fan-shaped masses of "branch" coral, great care having been taken to cement them firmly. A mass of coral is also fastened to the bottom of the pot, as shown in the cut. Around the centre of the pot is fastened a band of scallop shells of brightest colors. The coating of black

Fig. 1.

asphalt and the pure white of the coral, gives the pot a half-mourning look, which is broken up by coating it with algæ (sea weeds). Fifteen cents worth of Irish moss (*Chondrus crispus*) was purchased, and some *Sertularia argentia* obtained from Coney Island. These were made into small bunches, the ends of which were dipped into hot asphalt till a knob was

formed as in Figs. 1 and 2. These were stuck all over the asphalt and about the base of the coral wherever the asphalt was exposed.

Those who do not live near the sea

Fig. 2.

shore, where shells and sea weeds can be obtained, but who can procure the coral or have it on hand, should not think of using it and covering the asphalt coating with wood mosses and the burrs and cones of the woods, as no combination can be so out of place, out of keeping, and offensive to good taste, as sea shells and corals brought in conjunction with wood mosses and cones. These window ornaments at best would be condemned by a person of severe æsthetic tastes, but there is no excuse for deliberately burlesquing nature by having a mass of coral from the East Indies starting out from a bed of lichens from Maine.

You must follow the order and harmony of nature. For instance, take branches of the liquid amber (which in form and habit is very suggestive of coral) as a substitute for the coral; for the seaweeds use wood mosses and lichens; for the band of scallop shells, use a band of dried and pressed oak leaves, with acorns fastened on here and there. In this way you will obtain the rich grays, browns, and greens of the woods. If you have any preserved butterflies or beetles, by all means fasten on a few of them, but don't plaster all over with bugs. Don't torture nature like a barber I know of, whose place I carefully avoid, who decorates (as he thinks) his windows with sweet potatoes, turnips, beets, and carrots, scooped out, filled with water, and suspended upside down. The

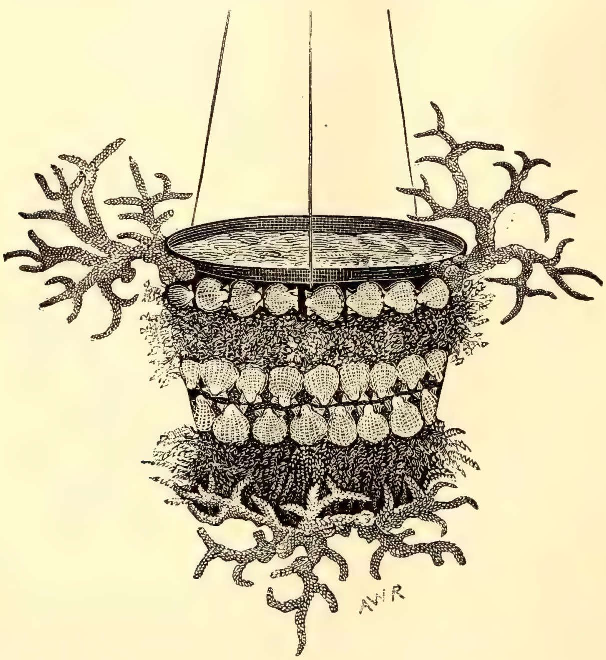

Fig. 3.

poor things produce sickly and abortive leaves, till they drop down, a decaying mass. And this wretched barber thinks this all wonderful and beautiful. I pray that the young readers of this journal will never be guilty of torturing such honest vegetables and good taste in this *barberous* way. But fix up your window as I have mine, and the ladies from far and near will exclaim, "Oh! isn't it perfectly beautiful."

The Hunted Fisherman.

BY A. W. ROBERTS.

I HAD now turned my attention to collecting fish and other aquatic animals, as well as plants. A small nest-building fish known as the three-spined stickle-back being in great demand, and selling as high as twenty-five cents a pair for breeders in good color, I determined to secure a good quantity of them from a pond situated a mile from the old homestead in Williamsburg, N. Y.

This pond occupied the same ground on Broadway where now stands the German Savings Bank, and Tuttle's coal yard, and was fed by a small stream that flowed in from Wallabout Bay through Johnston's woods, causing the water to be brackish. Up this stream the stickle-backs ascended every spring from the salt water of the bay to the fresh water to breed. When Broadway was laid out and graded, the stickle-backs became land-locked, and dwarfed in size, but, most strange of all, took to building their nests in communities, one male fish often attending many nests.

These fish were very shy, and, on the approach of any one, would retreat to deep water, where the hand net was of no use; so I constructed a small seine of mosquito netting, using bottle corks for the "cork line," and bits of lead pipe for the "lead line." For the "warp lines" I used two clothes lines; the "staffs" consisted of turned pickets.

The night I had set for trying the seine was cloudy, with now and then a bit of moonshine breaking through. Just the kind of night I desired, as the stickle-backs would not be so easily alarmed. So at one o'clock in the morning I might have been seen climbing out of my bed-room window to the roof of the kitchen, whence I reached the garden by a ladder previously placed in position.

Dressed in a suit of old garden clothes and shoes, and provided with two pails and the seine, I felt confident of securing at least one hundred and fifty before returning home, which would yield me $3.50; not a bad night's work for a youngster.

Reaching the pond at two o'clock, I felt safe from all intrusion and questionings from curious passers by, and possible discovery by other collectors, whom I had often noticed following me. This pond lay in the beat of a certain policeman, a very ugly, cross fellow, who was particularly "down" on all small boys, who, in lieu of a better name, christened him "Tight Lips." His beat being a very long one, I was in hopes that he would not come my way before I was through, or that he would take a nap in one of the engine houses.

The houses near the pond were few and far between; not a light was to be seen nor a sound to be heard, except the occasional croaking of a frog. I determined to make my first haul near the upper end of the pond, in the centre of which projected a large post. From this post I intended to work one end of the seine in shore again. Tying the end of one of the warp lines to a stone, I took off all my clothes preparatory to swimming out to the projecting post. I could not wade out, for the reason that at the bottom of the pond were numerous broken glass bottles, and years before this place became a pond, there was a brick kiln which had left deep pits, where the water now stood ten and fifteen feet deep.

So placing my shoes and clothing in the pails, I slid gently into the water, holding on to the end of the warp line with my teeth. I had but just reached the post, when I heard a policeman's club rattling a playful sort of tattoo against the numerous large rocks that bordered the foot-path of the road. In an instant I was all under water but my head, and that was securely hidden behind the post. I now waited breathlessly for him (it was "Tight Lips") to pass on, hoping that he might not observe my clothing standing on the bank; but just as he was about to

pass the spot, out burst the moon, flooding the pond and shore with light. In a moment he was busy examining my clothes by the light of the moon, evidently much puzzled. Fearing that his next move would be to secure the "warp line" of my seine, I began pulling hard and steady on my end, hoping that the line would slip off the stone easily and without noise, but alas! as I pulled I could see the stone sliding slowly and noiselessly toward the water, in its course upsetting one of the pails, and carrying the other with it. In moving the pails he must have placed them directly on the line. When "Tight Lips" saw this, he started for the top of the bank, frightened. Fortunately the "cork line" was well under water, as the seine hung in the very deepest part of the pond. Now, taking a rest, I determined to retain my present position till he walked away, but he wouldn't walk; he deliberately sat down on one of my pails to wait for further developments. In this position we remained for half an hour, he watching the pond and I watching him. It was evident he had not discovered my hiding place nor the seine. Soon he got up, and examining my clothes again, went through all the pockets, even closely scrutinizing my handkerchief in search of a name. The moon passing out of sight again, I pulled in the seine vigorously till it was all in by the post. By this time, feeling chilly and cramped from being in the water so long a time, and in one position, not to mention the stings of boat flies, and ravenous nippings of horse leeches that swarmed about me, I determined to sink the seine with stones, of which there were plenty, around the post under the water. So treading the net down to the bottom of the pond, I silently sank myself under the water to where the stones lay, placing them securely all over the net to keep it down. Making a calculation as to the value of my things on shore, I concluded to sacrifice them rather than be taken to the station house undressed, or to my father's, at that hour of the night, to be laughed at by my brothers the next day.

Some forty feet from where I stood projected forth a long dark shadow cast by a tall factory situated on the opposite shore of the pond to where policeman sat. If I could reach that shadow unobserved, I would be all safe. So inflating my lungs to their fullest capacity, I settled down to the bottom of the pond, and struck out vigorously under water in the direction of the friendly shadow. Knowing by the change of light that I had entered it, I rose to the surface, taking great care to keep my face turned away from where the policeman sat, and not to puff too loud in allowing the escape of exhausted air from my lungs. Now remaining perfectly motionless for a few minutes, and working the corner of one eye round, I obtained a peep at the reclining policeman. He still remained just as I had left him before I went under. I now ventured to move ahead, going very slowly. I was doing nicely, when whop! came a big stone right near my head. It was evident he had discovered me; my only chance was to gain the shore as quickly as possible. As the pond occupied an entire block, he would have to run around it before he could reach me. The stones fell thicker and faster. He called to me "To come out or he would take me in." I answered back that I could'nt get out any faster. In a minute more I had reached the shore and was dashing up Lorimer street at full speed for home, then down Remsen street, he following close behind. Reaching the "corn lot," over the high fence I vaulted, then through the tall corn, across the garden, over the kitchen roof by the ladder (which I drew up after me) and into bed, feeling that I had had all I desired of "fish hunting" for one night.

To be continued.

Lessons in Magic—VII.

The Flying Watch.

"WILL some lady be kind enough to lend me a white kid glove?" the performer asks. "Ah, here is one; thank you, madam. You are not a confederate of mine, are you?"

"No."

"Then I wish you to see me tear this glove to pieces, else the audience will say afterwards, either that I changed it, or that you were my assistant."

And so the glove is torn, and the pieces thrown on the stage. Again the performer wants to borrow.

"Will some gentleman lend me a watch? Thank you, this will do."

As he takes it, however, it strikes the hour, and informing his audience that a *repeater*, though useful to a politician, will not answer his purpose, he returns it. He tries two or three, but, strange to say, they are all *repeaters*. Failing in getting another kind, he places the last one offered, with the fragments of the glove, into a pistol which is furnished with a funnel-shaped tube, and aiming at a piece of black cloth, which his assistant holds, he fires, and at the same moment the watch and glove appear suspended on the cloth.

When the performer borrows the glove, he takes it with the fore-finger and thumb of his right hand, makes it into as small a roll as possible, and then with tips of his fingers, places it in his palm. At the same moment he allows a second glove to appear, which he has had concealed under his second, third and little fingers, which until now he has held closed. This glove he passes from his right to his left hand, and if the change is made rapidly, it will never be detected, but the audience will still suppose that they see the same glove that was borrowed.

It is this second glove that is torn up after the borrowed one is concealed. To conceal this without being detected is no little art, and unless explained my readers may be at a loss how to do it. When the performer comes down into the house to borrow the glove, he carries his *wand* in his right hand, apparently for the sake of effect, but really as an excuse for keeping the hand closed, as the second glove is concealed in it. When about to take the glove from the lady, he tucks his *wand* under his arm, and then after the change is made, he takes it in his right hand again, and, as if to get it out of his way, thrusts it into his breast pocket, and the borrowed glove with it.

The watches which strike the hour, do not strike at all, but the striking is done by a repeating apparatus, which is worked by pressing a small button. This apparatus, which is no larger than a watch, is concealed about the person. I have always worn it under the waistband of my trousers, the button turned in. When I wanted it to strike, I distended my belly—don't be shocked—and as long as the pressure on the button was kept up, just so long the striking would continue. Others wear it on the muscular part of the arm, and, by throwing out the muscle, press the button, but I think my method better than any other.

When the performer returns to the stage to get the pistol from his assistant, he hands him the borrowed watch and glove. These, the assistant fastens to the upper part of a piece of cloth, and then folds the cloth so as to conceal them. The pistol which receives the substituted watch and glove, is a very simple affair, being an ordinary weapon to which is fitted a large brass or tin funnel; inside this funnel is a tube which fits into the barrel of the pistol, and comes nearly to the mouth of the funnel. It is between this tube and the sides of the funnel that the articles are packed, and of course they are not affected at all by the discharge of the pistol.

To make the articles appear on the cloth, the assistant merely drops the fold of the cloth at the moment the performer fires.

The repeating apparatus, any ingenious watchmaker can make, or it may be purchased where other magical apparatus is sold.

This trick is somewhat similar to another very popular one known as

The Broken Plate.—In this trick, the performer begins by sending his assistant into the house to borrow two or three watches. These he receives on a china plate, and as he returns to the stage, he unfortunately trips, and, falling, smashes to atoms the plate and watches.

The performer regrets this accident, not so much on account of the damage done to the watches, "For those," he says, "I can easily replace by others equally as good. But as for my plate, it is a loss which I fear, I can never make up, as it is one of a set of china which has been in my family for many centuries. There is a superstition too connected with it, that whenever a piece is broken, some calamity is about to befall the owner. In this in-

stance, you see, the superstition has proved correct, for surely it is a great calamity to have to pay for three such watches as those that my assistant just borrowed."

"However," he continues "I must do the best that I can under the circumstances, and as there is no use of blowing up my asistant, I will try the effect of blowing up these fragments."

He then collects carefully, all the fragments of the watches and plate, and places them in the funnel of a gun.

"Now that I have got the pieces together," he says, "I must find some wadding for my gun. Ah! here's good blowing material. The New York *Herald*, that will do first rate, but I still want more." Here he looks about the stage, and then discovering another paper, holds it up and reads.

"Ah, what have we here? The New York *Tribune*. In that goes too, and now if there ain't an explosion, its because gunpowder won't burn, for when those two papers come together, its worse than that terrible time we have read so much of 'when Greek meets Greek.'"

He turns the gun toward the audience, and they see that it is loaded to the muzzle.

He next calls their attention to a large gilt frame which is hanging from the ceiling by two cords. Inside this frame instead of a picture is stretched a piece of black velvet. He informs the audience that "This is a picture of Brooklyn on a moonlight night, but the moon not having risen and the gas not being lit, I am afraid you hardly have a very distinct view of the city."

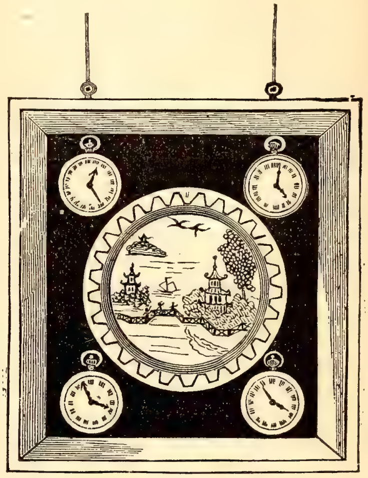
"I now propose to fire the contents of that gun at this picture, and the moment I do so, the city will be illuminated, whilst the watches will be found in the pockets of the owners."

He picks up the gun, which has been lying on a table, aims and fires it at the frame, and on the instant, the plate and watches appear in the velvet as in the illustration. He turns the gun again toward the audience, and shows that it is empty.

The watches he takes from the frame and returns their owners.

A very pretty effect is sometimes introduced by discovering the plate to be imperfect in one place where a piece is out. This piece is picked up on the stage, and when the performer appears to throw it at the frame the imperfection instantly disappears and the plate is perfect.

For this trick you will need two or three brass watch cases, some springs, wheels,



and other watch material, a frame properly prepared, and a peculiar pistol or gun.

The pistol is different from any that I have described, inasmuch as it is furnished with two funnels instead of one; these funnels fit one within the other, and it is in the inner one that the watches, papers, etc., are placed.

When the performer calls the attention of the audience to the picture, he places the pistol on the table, and whilst they are engaged in looking at the frame, the assistant takes out the inner funnel of the pistol, and puts it on the "servant" or shelf at the back of the table; sometimes the performer does this himself before picking up his weapon.

The frame is a shallow box lined with black velvet, and with a velvet curtain falling down in front; this curtain is fastened to a roller, at one end of which is a spring arranged in such a way that the roller will revolve and the curtain fly up, unless held down in some way. A little

catch is at the bottom to keep the curtain down, and a thread is attached to this catch so as to release the curtain at the proper moment. The frame is fastened to the front of the box to give it a finish.

After the assistant has collected the watches, he places his hand over them to guard them, and then as he is returning to the stage, purposely falls, and at the same moment drops the plate together with the brass cases, wheels, etc., which he has held *under the plate* in his hand, whilst the borrowed watches he carefully secures and secretes in one of his pockets. Pretending to be hurt, he limps off the stage, and immediately fastens the plate and watches to the back or rather bottom of the box, pulls down the curtain, fastens the catch, and then carries the frame on to the stage and hangs it to the cords.

When the performer fires the gun the thread is pulled by the assistant, up flies the curtain, and there hang the watches and plate.

The broken piece, is merely a little piece of black silk fastened on to the plate, and this is pulled away at the moment the performer pretends to throw the bit of plate that he has picked up.

Editorial Notes.

Removal.

FOR many years our quarters at 176 Broadway have been too small for our business, and we have been in many respects subjected to great inconvenience thereby. The difficulty and annoyance of moving at a busy season of the year, has hitherto prevented us from making a change, but at last we find ourselves compelled to secure more room and additional facilities. We have therefore leased very large and commodious premises at No. 14 Dey street, about one block from our old stand. Our office and reception rooms will be situated on the second floor (the one immediately over the store), and we propose to have them fitted up in very attractive style.

Please remember the change of address after the first of May.

(6) Sept. 10—Apparent diameter, 28″; thirteen days before inferior conjunction.

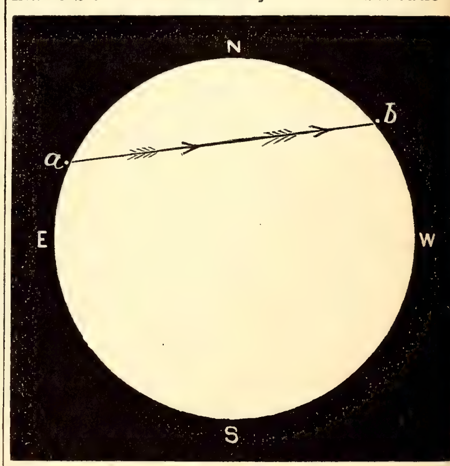
about the 30th. On the 20th she will be directly north of Sirius, and with Betelguese on the S. W., and Procyon on the S. E., will form a large diamond having sides about 26° long. The figures in diagram (Fig. 1) show the phases through which she passes in the four months, from May 10 to Sept 10.

It will be seen that on Sept. 10 her apparent diameter will be four times what it is May 10; in other words, she is apparently *sixteen times* as large. The illuminated portion will be towards the sun in all cases. Any small telescope or good opera glass will reveal these phases, and if the instrument be a good one, a low power should be used, as small telescopes have detected in Venus what the most powerful instruments have failed to reveal. Galileo was the first man who saw these phases, and thus by the aid of his simple, home-made telescope, this great man demonstrated the truth of the Copernican theory.

THE MOON.—The Moon will be in conjunction with the planets as follows:

May 1—South of Uranus about 4°.
" 14—North of Jupiter " 5°.
" 14— " Mars " 6°.
" 17— " Saturn " 8°.

The Moon will occult the first magnitude star Antares June 3, the Moon being nearly at the full at the time. The cut shows the points of immersion and emersion, for the latitude of



(*a*) First contact, 10h. 56m. evening 3d.
(*b*) Last contact, 0h. 2m. morning 4th.

OCCULTATION OF ANTARES BY THE MOON, JUNE 3–4.

Washington. (The data for this occultation are taken from the "American Nautical Ephemeris," and Washington mean time is given.) The star contacts the Moon's eastern limb at 10h. 56m. evening, remains behind the Moon 1h. 6m., and emerges at her western limb at 0h. 3m. morning of the 4th.

Penn Yan, N. Y.

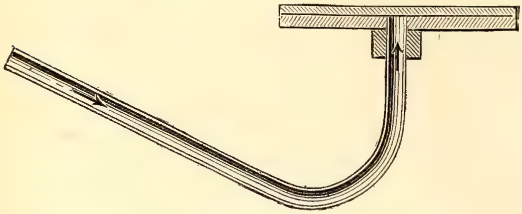
Ebonized Wood Furniture.

There are two kinds of black stains for wood. First, the ordinary black stain for different kinds of wood. Second, the black ebony stain for certain woods which approach nearer to ebony in hardness and weight. The ordinary black wood stain is obtained by boiling together blue Brazil wood, powdered gall apples, and alum, in soft water until it becomes black. This liquid is then filtered, and the objects painted with a new brush before the decoction has cooled, and this repeated until the wood appears of a fine black color; it is then coated with the following liquid:—A mixture of iron filings, vitriol, and vinegar is heated (without boiling), and left a few days to settle. If the wood is black enough, yet for the sake of durability it must be further coated with a solution of alum and nitric acid, mixed with a little verdigris, then a decoction of gall apples and logwood dyes are used to give it a deep black. Soft pearwood is preferable to all others for black staining. For the fine black ebony stain, apple, pear, and hazel wood are the best woods to use; when stained black, they are most complete imitations of the natural ebony. For the stain take—gall apple, 14 oz.; rasped logwood, 3½ oz.; vitriol, 1¾ oz.; verdigris, 1¾ oz. For the second coating a mixture of iron filings (pure) 3½oz., dissolved in strong wine vinegar, ¾ of a litre (1½ pint nearly), is warmed, and when cool the wood already blackened is coated two or three times with it, allowing it to dry between each coat. For articles which are to be thoroughly saturated, a mixture of 1¾ oz. of sal ammoniac, with a sufficient quantity of steel filings, is to be placed in a suitable vessel, strong vinegar poured upon it, and left for fourteen days in a gently heated oven. A strong lye is now put into a suitable pot, to which is added coarsely-bruised gall apples and blue Brazil shavings, and exposed for the same time as the former to the gentle heat of an oven, which will then yield a good liquid. The woods are now laid in the first-named stain, boiled for a few hours, and left in it for three days longer; they are then placed in the second stain and treated as in the first. If the articles are not then thoroughly saturated, they may be once more placed in the first bath, and then in the second. The polish used for wood that is stained black should be "white" (colorless) polish, to which a very little finely-ground Prussian blue should be added.—*R. Pearson.*

—Ice is now being manufactured in Tennessee, Georgia and other Southern States, at one cent per pound.

The Pneumatic Paradox.

This singular experiment was first brought to the attention of the public about fifty years ago, and although known to readers of technical journals, seems to have escaped the notice of the writers of our ordinary works on natural philosophy.



THE PNEUMATIC PARADOX.

The only materials required are two discs of card or wood, and a tube which may be of glass, metal, or even tobacco-pipe stem.

From a stiff card cut two discs or circles about two and a half inches in diameter. One is to be left plain, and through the centre of the other punch a hole the same size as the outside of the tube. Then fasten to the under side of the card, with sealing-wax or paste, a piece of cork with a hole in it the same size as that in the card. This is to make a bearing for the insertion of the tube.

To make the tube, the best material is a piece of glass tubing about a quarter of an inch in diameter. This may be bent in the flame of a common spirit-lamp, and inserted in the cork, as shown in the engraving, when the apparatus will be complete. Where glass is not procurable, any tinsmith can make a tin tube that will answer the same purpose. If carefully bent over the thumb, it may be curved without flattening or wrinkles; but those who do not succeed in this way may first fill it with sand or melted rosin, and it may then be bent without danger.

Having constructed this very simple little apparatus, it will be found that the utmost power of the lungs will fail to blow the upper disc off the lower one. Nay, more: If the position of the instrument, as shown in the figure, be reversed, so that the disc attached to the tube shall be uppermost, and the loose one below it, it will be found that on blowing through the tube the loose disc will not fall away from the other one, but will adhere strongly to it! The loose disc may even be attracted from a short distance, say half an inch, and actually raised up by the stream of air which presses against it from above!

This little apparatus, which any boy or girl can easily make, may give rise to a good deal of amusement. Most persons, if asked if, by the force of their lungs, they can raise a cent laid on the upper card, will answer "Yes" On trying it, they are sure to fail, and at first think that it is the cent that keeps the card down. They will be greatly surprised to find that they cannot lift the bare card, and still more astonished when they see that it is totally impossible to blow the loose card away, even when the instrument is turned upside down, as we have just described.

The principles involved in the action of this little instrument are not very easily explained, and although many plausible solutions have been given, a good deal of uncertainty still hangs over the subject.

BOOK NOTICES.

The Ornamental Penman's, Engraver's, Sign-Writer's and Stone-Cutter's Pocket Book of Alphabets. London and New York: E. & F. N. Spon.

This is a neat little oblong 12mo volume, containing thirty-two plates of alphabets. It will prove specially valuable to those who wish to finish off their drawings handsomely by a neat title, for it is a fact well known to every draughtsman that while a poor drawing, well lettered, may present a tolerably respectable appearance, the very best drawings may be spoilt and rendered repulsive by poor lettering. One great point in favor of this little book is its moderate cost.

Practical Instruction in Animal Magnetism. By J. P. F. Deleuze. Translated by Thos. Hartshorn. Revised edition, with an Appendix of Notes by the Translator, with Letters from Eminent Physicians and others descriptive of Cases in the United States. 12mo, pp. 524, cloth. Price $2. New York: Samuel R. Wells & Co.

This subject is one to which we have given very little attention, and consequently we do not feel able to pronounce an opinion in regard to the value of this work. It is a large volume, neatly got up, and for those who desire to study the subject, we should consider it a most desirable work.

Section Cutting. A Practical Guide to the Preparation and Mounting of Sections for the Microscope; Special Prominence being given to the Subject of Animal Sections. By Sylvester Marsh. Reprinted from the London edition. With Illustrations. 12mo., cloth, gilt title. Price 75 cents. New York: Industrial Publication Company.

The majority of the most important objects studied by the microscopist, demand for their thorough examination that they be reduced to thin sections. The ordinary works on the microscope are somewhat meagre on this special branch of laboratory work, and Dr. Marsh has

done good service by giving simple and yet very complete directions for all the operations connected with section cutting. To the American edition has been added notes equal in amount of matter to quite half the original work. These not only explain such English terms as *Rangoon oil*, etc., but give a very complete and fully illustrated article on the selection and keeping in order of section knives.

Practical Hints.

Liquid Glue.—Dilute officinal phosphoric acid with two parts, by weight, of water, and saturate with carbonate of ammonia; dilute the resulting liquid, which must be still somewhat acid, with another part of distilled water, warm it on a water-bath, and dissolve in it enough good glue to form a thick, syrupy liquid. It must be kept in well-closed bottles.

Coppering Iron or Steel.—The following process is said to give very good results: First make the article entirely bright by file, scratch brush, or any of the usual modes. Apply to the surface a coating of cream of tartar, then sprinkle the surface with a saturated solution of sulphate of copper, and rub with a hard brush. The coating of copper deposited on the iron is said to be very even and durable.

Cleaning Glass Bottles.—It is stated that glass bottles may be quickly and thoroughly cleansed from all traces of adhering fatty or oily matters by the use of a concentrated solution of permanganate of potash to which a few drops of hydrochloric acid are added. The solution is employed by washing and rinsing. The hydrochloric acid sets free a little caustic potash, which in some way appears to be more active in its effect upon the oily or greasy matters than,when presented in the ordinary way. We wish it understood that we do not vouch for the value of this recipe. We reproduce it from the *Druggists' Circular* merely as a hint which may be cheaply tried.

Standard Measures.—The standard yard, now in use in the United States, was taken from the English standard yard; but it was subsequently shown that this standard, as deposited in the office of weights and measures at Washington, was incorrectly taken off—it being 0.00005803 longer than the English imperial standard yard. This difference was no doubt due to incorrectness of the divisions on the original scale, or derived from insufficiently delicate appliances for reading off the measure from the English standard.

It cannot be expected that the divisions on the English scale could be very correct, from want of knowledge in those days to make a correct screw, which is yet a difficult problem, even with our advanced knowledge of mechanic arts. But as it was originally intended to have the English and American standards of length alike, we ought not to acknowledge any difference.

The Smithsonian Institution published tables in 1859, comparing the length of the English and American foot measures, which makes the American yard 2-1000th parts of an inch longer than the Imperial standard yard, or a difference of four inches per mile. The United States Coast Survey are now using a corrected American standard yard, the same length as the Imperial standard yard.—*Journal Franklin Institute.*

Bronzing Wood, Leather, Paper, Etc.—The *Moniteur Industriel*, of Paris, describes a process for bronzing wood, leather, paper, etc., as follows: The inventor dissolves gum lac in four parts by volume of pure alcohol, and then adds bronze or any other metal powder in the proportion of one part to three parts of the solution. The surface to be covered must be very smooth. In the case of wood, one or several coats of Mendon or Spanish white are given, and the object is polished with an iron of proper shape. The mixture is painted on, and when a sufficient number of coats have been given, the object is well rubbed. A special advantage of this process is that the coating obtained is not dull, but can be burnished. A transparent varnish is applied to preserve the metallic appearance thus obtained.

Washing Glass.—The following hints apply to glass slides used in microscopy, as well as to chemical vessels. A correspondent of the *Chemical News* says: Such a subject may seem too simple, but yet the more I see students at their work, the more I am impressed with the fact that but few know how to wash a beaker-glass clean. Some time since I took beakers from various students in my laboratory (which they had washed and put away), and held them under a powerful stream of water until they were thoroughly wet. On taking them from under the spout, in almost every case the water ran off the glass in spots, showing that the glass was greasy. The best thing to wash beakers, etc., with, according to my experience, is sand-soap. Naturally, the sand must not be sharp. The soaps containing infusorial earth are most excellent for this purpose. Borax soap is also very efficacious. A piece of board about 20 cm. long, 15 cm. wide, and 4 cm. thick, should be screwed on to the right (inside) of the sink. In this block a rectangular hole, about 2 cm. deep, and 1 cm. smaller than the section of the soap when stood on its long end, is to be cut. The bottom of the cake of soap is then whittled away so that it fits tightly in the hole. It is now moistened and pushed into the aperture, where it remains tightly fixed. By wetting the right hand thoroughly, and rubbing on this soap ridge, a good lather is made. With the soapy hand the glass is rubbed and washed until. on taking it from under the stream, no oily spots appear, the glass appearing wet all over. The beaker is then dried with a good towel ("glass towel"), and finally polished with a piece of chamois or kid leather. The final polish with kid is necessary, since the best towel leaves fibres on the glass. In cleaning test tubes, it is only necessary to rub the probang on the soap.

EXCHANGES.

Yearly subscribers to the Young Scientist have the privilege of inserting three exchanges (or one exchange three times) during the year. This privilege is strictly confined to *exchanges; buying and selling* must be carried on in the advertising columns, where the charge is 30 cents per line. Each exchange is limited to thirty words, making about four lines, and in order to receive attention must be written on a slip of paper by itself. We file all letters received, and have no time for copying out exchanges and queries.

As we desire to make the journal of the utmost value to *all*, and not merely to serve the interests of individuals, we shall strictly adhere to these rules, which are certainly liberal, giving as they do advertising to the value of $3.60 free to each subscriber.

Wanted, a collection of Southern woods, for a collection of New Hampshire woods; will exchange for rough pieces. W. P. Adams, Pittsfield, N. H.

For exchange, a guitar, patent head, nearly new, cost with strings $14—splendid instrument, in good order; state what you have to exchange. W. Z. Allen, Monrovia, Ind.

A No. 1 self-inking Official press, costing $10, and $13 worth of type and fixtures, to exchange for a combined bracket saw and lathe, or offers. C. A. Bacon, Elba, Lapeer County, Mich.

To exchange, Bourne's "Treatise on the Steam Engine," cost $5, for chemical apparatus and chemicals of the same value. E. T. Birdsall, 39 East 22d street, New York.

Wanted, 350 or 400 different kinds of foreign stamps; state what is wanted in exchange. John S. Briggs, Newark, N. Y.

Wanted, January and March (1878) Nos. of Young Scientist in exchange for the "Mineralogist Companion." Walter Brockstedt. 2118 Carondelet Avenue, St. Louis, Mo.

Printing press, cost $35, and several fonts of type, in exchange for anything pertaining to science, literature or art. E. S. Dayton, Basking Ridge, N. J.

To exchange, one telegraphic key and sounder, in good shape; also a new scroll saw; state offers, John Duff, Jr., Pontiac, Ill.

Two Bunsen batteries to exchange for engraver's tools, or Vols. 1 and 2 of Scott's "Coin Journal," or old U. S. coins. Clark Horn, Jr., Box 582, Scranton, Pa.

An oscillating steam engine, 1-inch bore, 2-inch stroke, for a Queen's Household microscope, or offers. L. Kent, Santa Anna, Los Angeles Co., Cal.

Wanted, in exchange for valuable books (of which lists will be sent on application), Packard's "Guide to the Study of Insects," edition of 1876. C. H. L., 57 North 1st street, Edgefield, Tenn.

To exchange, cocoons of Attacus Luna, Cecropia and Polyphemus, for specimens of entomology or geology. Geo. A. Lippincott, Box 50, Watsontown, Northumberland Co., Pa.

A new stationary steam engine of ½-horse power, worth $30, in exchange for a good watch, or almost anything; mention offers. H. Mackenzie, Jr., Petroila, Ontario, Canada.

To exchange, complete set drawing instruments, cost $3; state offers. J. Mueller, 2453 Kosciusko street, St. Louis, Mo.

In exchange for books, a Novelty printing press in excellent condition, prints a form 6½x10½ ins.; cost $32, ink roller cost 75c., and $1.50 worth blue ink. J. A. Osborn, Scientist, Mahmal, Cambridgeport, Mass.

To exchange, a Novelty printing press, type and accessories, for a microscope with accessories, or minerals, or offers. T. W. Patterson, Warsaw, N. Y.

Will exchange one or more of my new extension step fruit ladders, the "Climax," price $2.50, for merchandise. H. E. Phelps, Marshall, Mich.

Wanted, an achromatic photo camera, a good shotgun, or scientific books or apparatus, in exchange for a fine scroll saw in good condition. A. B. Porter, 501 N. Tenn St., Indianapolis, Ind.

"The History of Our Country," by Benson J. Lossing, cost $15; also other books to exchange for scientific and practical books and apparatus. H. M. Rauschkolb, 246 Delord St., New Orleans, La.

Telegraphic key and sounder, finely wrought on proper base, cost $8; will exchange for good revolver. S. G. Reese, Box 133, Elizabethtown, Lanc. Co., Pa.

To exchange, one set of Lily carving tools of three pieces; state what is offered in exchange. B. M. Rockwood, Franklin, Mass.

Wanted, a first-class work on entomology, with colored plates, for Stanley's Travels, calf bound, nearly new; also other books and minerals to exchange. H. Salisbury. Box 399, Whitewater, Wis.

Wanted, a coachmaker's vice, opening 8 or 9 in., in good order, or a lot of thumb screws, in exchange for an E-flat cornet worth $15, or violin worth $12. B. H. Smith, New York Mills, Oneida County, N. Y.

Wanted, a Seltz's boys' theatre; state what is wanted in exchange, and give full particulars of the style of theatre. H. C. Spaulding, 7 Princeton street, Boston, Mass.

Kane's Arctic Explorations, for a small printing press with type and ink. H. B. Taylor, Tehuacana, Limestone Co., Texas.

A game of parlor billiards, cost $4, will be given in exchange for something of equal value. J. H. White, Canajoharie, N. Y.

Back numbers of "Youth's Companion," for the years 1877 and 1878, in good condition, to exchange for chemicals, chemical apparatus, or offers. F. Willis, 3 Myrtle street, Boston, Mass.

THE

YOUNG SCIENTIST.

Published Monthly at 50 cents per year.

Postage free to all parts of the United States and Canada, except New York City, where the law requires 12 cents extra postage, making the subscription in New York City 62 cents.

Postage stamps taken at full value, but only for amounts less than $1.00. One and Two-cent stamps preferred.

TO ADVERTISERS.

The Young Scientist has been received with so much favor that its circulation is already greater than that of any other monthly Scientific or Mechanical journal published in the city of New York. It goes into the best families, and has their confidence. No clap-trap advertisements, or advertisements of patent medicines received at any price.

Advertising Rates—30 cents per line, agate measure.

All Communications should be addressed to

THE YOUNG SCIENTIST,

P. O. Box 2852. 176 Broadway, New York.

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

Vol. II. NEW YORK, JUNE, 1879. No. 6.

The Hunted Fisherman.—II.

BY A. W. ROBERTS.

THE next night I again visited the pond, accompanied by my "big brother," our bulldog, and a written permit from the owner of the pond, granting me permission to fish night or day.

I had also extemporized a bathing suit, which consisted of an undershirt and a pair of heavy flannel drawers, to protect me from the leeches and boat-flies. After reaching the pond, we got right to work, and on the first haul, one hundred and fifty sticklebacks were taken, and thousands of boat-flies, which, almost before we could place them in the pail, flew back to the pond. The second haul consisted of two hundred more fish and many masses of nests.

We now prepared to return home, having all the fish that I could take care of. I felt thankful for not having met the policeman, who, in all probabllity, was taking a nap, somewhere on his beat.

The day previous I had taken possession of all my mother's wash tubs, and placed in them a flooring of sand some three inches deep, and several bunches of plants. All the nests were placed in one tub, in the hope that the eggs might hatch out, but at the expiration of three days they had turned "blind," and were soon covered with fungus. This was caused by a want of circulation of the water over the eggs.

Noticing that the male sticklebacks were beginning to show bright colors, I concluded to take my first lesson in fish culture.

Up in the hayloft was a box of window glass; taking a number of panes of glass, I formed in each tub a series of compartments, in the following manner: From the centre of each tub the panes of glass radiated till they came in close contact with the sides of the tub, thus forming a series of acute angles; the bottom edges of the glass were crowded down through the three inches of sand till they rested firmly on the bottom of the tub, and well into the apexes of the angles a bunch of mermaid weed was planted; this also helped to sustain the glass compartments,

as well as to keep up a thorough oxygenation of the water.

In each compartment I placed a pair of sticklebacks, giving them a meal of angle worms before leaving them for the night. Next morning, when I examined the tub, to my great surprise, many nests had been built during the night; in some of them the bright yellow eggs showed plainly through the openings of the nest. Every nest was being vigorously ventilated by the male fish, who were hard at work fanning a current of water on them with their pectoral fins. In other compartments the male fish were tearing off small pieces of confervæ that grew on the mermaid weed, which they carried in their mouths to the nest, packing it down with their noses. After several mouthfuls had been disposed of in this way, they fastened the pieces together by pressing them down more compactly with the under side of the body, at the same time exuding a marine glue, so to speak, that cemented all together securely. In the centre and on the top of each nest were four orifices, and into these the male, after a considerable display of anger, and much driving, at last drove the female, her head projecting far enough out to allow her to breathe. In a few minutes the male drove her out of the nest head first, he now passing through the nest, and over the eggs, just to see, you know, if Mrs. Stickleback had laid her eggs in the proper place, and to make things all right. In an instant he was out, flaming all over with blue, green and orange, his eyes looking like small torquoise. When the eggs became too much exposed through the openings of the nest, he contracted them by cementing on more confervæ. Over the nest he remained day and night, changing from one opening to another, constantly fanning a current of water through them. Whenever poor Mrs. Stickleback showed herself, her mate drove at her fiercely, biting her till she was glad to hide in the mermaid weed. The trouble was that she would have eaten all the eggs if she had had a chance, and he knew it. For this reason I took all the females out as soon as they had deposited their eggs. As each nest was completed, and the eggs deposited, I withdrew the glass partitions, but terrible battles taking place between the males, I had to place them back. Even then they would try to fight each other through the glass. When all the eggs were hatched out, and the bottom of each compartment seemed alive with young sticklebacks, I removed all the male fish and glass partitions, and in a few weeks was the happy possessor of a large "school" of inquisitive, restless, baby sticklebacks.

For collecting, the best kind of a net is what is known as a "scoop net." The handle should be from six to eight feet long, and an inch and a half in diameter. The ring, or scoop, is made of No. 00 wire, thoroughly welded together at the shank. The inner diameter should measure twelve inches. The end of the handle, where the jointed shank is to be driven in, is protected with a ferrule to prevent it from splitting.

The best material for making what is known as the bag of the net is "bobbinet netting," sometimes called by dealers "army netting," shown in Fig. 1. The bag should not be less than 14 inches in depth. When using this net, always have a needle and thread with you, in case of the seams giving way, or holes being torn in it.

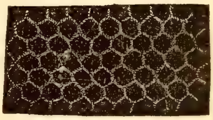

Fig. 1.

Fig. 2 consists of No. 00 wire, bent as shown at A A A A. The top piece, D D, is a piece of wood bound to the ends of the bent wire, A A A A, with strong twine. This piece of wood helps to float the frame of the net in an upright position when in the water. At the mouth of the bag of bobbinet a stout band of muslin, C C, is sewed to the netting, otherwise if the netting was sewed to the iron frame it would cut and tear away in a short time. To the outer edge of the muslin band, tape ties are sewed, two and a half inches apart. With these tape ties the bag or net is

securely fastened to the iron and wood frame.

At B B B are fastened ropes five feet in length. These ropes are for the purpose of holding the net in an upright position when it is drawn through the water, or to make the strain equal on all parts of the net. The ends of these ropes are brought together to a point to which the "warp" line is tied.

If the pond is large where you are going to collect, the best way to use this net is to tie the end of the warp line to a stone or tree, and then cast the net as far out as the line will allow. When the net sinks, and the piece of wood floats, it is in an upright position—haul in. Another way is to tie a stone to the end of the warp line, and cast the stone over the pond to the opposite shore; then setting the net in position in the water, proceed to the opposite shore and pull the net across the pond.

Small streams can be worked very effectually with this style of net, in the following way: Set the net across the stream, in the deepest part, being careful that the bottom of the iron frame rests closely on the bed of the stream, so that no fish can pass under. Now, drive two stakes into the banks of the stream; brace the net to an upright position by tying the side ropes of the net to the stakes. In case the frame of the net is too short to reach across the stream, build up "wings" of rocks, sods and moss, or of brush. These wings will lead the water of the stream and the fish into the net. When the net is securely set, take a lot of brush, to which tie a section of the warp line; now walking down stream, towards the net, everything is swept into it.

I would, however, caution my readers that this method of capturing fish is only to be adopted where specimens are to be captured alive, either for stocking other waters, or aquaria, or for purposes of scientific investigation. I would not have described such an unsportsmanlike way of capturing fish, had it not been that it is already well known to those who are likely to make a bad use of it, and so we may as well give our young scientific friends the benefit of it. Bear in mind that those who adopt this system, except for the purposes mentioned above, are, in most States, and particularly in New York, New Jersey, and the New England States, liable to severe legal penalties.

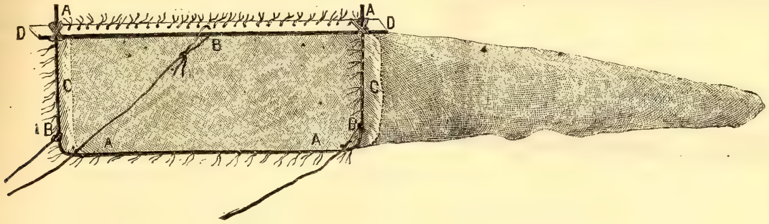

Fig. 2.

This method, however, has the advantage that it enables you to capture everything, without injuring them in the slightest degree. Therefore, after having selected the specimens you desire, always make it a point to return the others to the pond or stream. If even the smallest sized trout is caught in the net, be generous to this lovely fish, and gently put him back into his native element. Never mar your day's enjoyment by taking one home for your aquarium, where he will drag out a wretched existence for a few hours, and die from the high temperature of the water; or jump out of the tank only to be eaten up by the cat. Even if you capture a good sized one, do not take it home to fry, but think what a mean, sneaking way you have captured him. Take all the other kinds of fish you have use for, as they are the natural enemies to trout, their eggs and fry. Then, when spring and summer days come on, and you and your friends wish a quiet day's trout fishing, you can enjoy the finest sport in the world in your own neighborhood.

Scroll Sawing—II.

BY F. T. HODGSON.

FIG. 7 shows a spring steel saw frame, which is a great favorite with some amateurs; it will hold saws from two to five inches in length, and will face them in any direction, which is a great advantage, and makes this saw one of the best of its kind. Frames of this sort can be obtained that will take in a sweep of from eight to fourteen inches, for

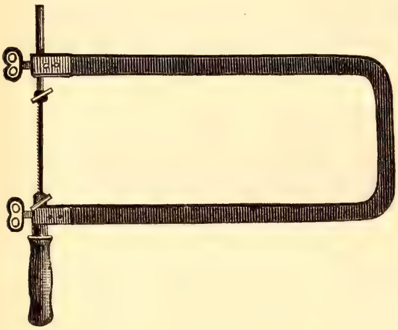

Fig. 7.

about one dollar, for the smaller size, and one dollar and fifty cents for the larger. This style of frame is, perhaps, the best in the market, as it is strong, neat, light, and efficient.

Fig. 8 represents a Swiss saw-frame, but, as the largest of them will only take in about six inches of a sweep, they are not adapted for general work, although

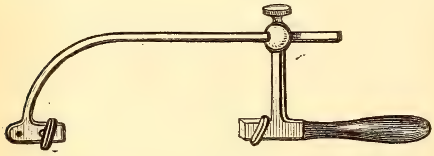

Fig. 8.

where it can be afforded, they will be found very efficient in cutting out small designs, as they are easily adjusted, and the saw can be strained to almost any tension.

Before closing this description of saw-frames for hand work, it will not be out of place to make mention of a very ingenious device that has lately appeared in the market. Fig. 9, will convey some idea as to the shape of this new frame, though

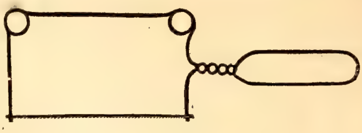

Fig. 9.

this is not the only one it assumes. It is made of spring steel wire about one quarter of an inch in diameter, and is in one continuous piece, the upper corners being turned double, and the narrow part of the handle twisted to hold it together at that point. The ends of the piece are sawed, so as to allow the saw to slip in. The saws used in this frame require to be turned on the ends to keep them from pulling through the slots in the ends of the wire. It has a sweep of about four inches, and can be purchased, with saw complete, for about twenty cents. The tension is obtained by springing the upper arm of the frame until the saw can be put in place, and when the whole is released the frame will spring the saw taut.

The next thing to be considered is some device by which the work can be held while operated on. Of course, the best device for this purpose, is a small carpenter's bench such as was shown and described in the YOUNG SCIENTIST last October, page 126, but as most young people would prefer using an ordinary dining table as a base of operations, it will be necessary to describe how this can be done with advantage. Procure a piece of hardwood board—maple or walnut—about one inch in thickness, twenty inches long, and fourteen inches wide. Bore two holes through the piece, as shown in Fig. 10, one, about four inches from the end, and the other about three inches from the reverse end. Cut V shaped notches up to these holes in about the proportion shown. The third notch is designed for very fine work and has no hole at the extreme end; it will be noticed that the angle of the slot is very acute. On the end of the piece where only one notch is cut, will be seen a short stubby screw, the head of which, by the aid of a screwdriver can be screwed

down until it is below the surface of the board; this screw can be used for holding thin stuff while it is being planed, polished, or sandpapered, as it can be raised to suit any thickness. Workmen call this temporary work bench "a horse," which is a

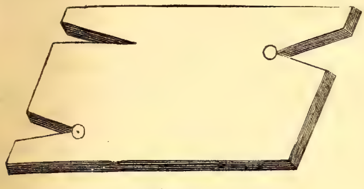

Fig. 10.

very appropriate name. It is fastened to the table by a screw-clamp, vice, or hand-screw; the last named being the better of the three because of its being made of wood, and, therefore, the least liable to injure the table or the "horse." There are many other devices for holding the work in place while being operated on besides the ones mentioned, but they are mostly of a complicated character, and too costly to be within the reach of the young amateur whose means are limited, therefore, no further reference will be made to them.

Besides the saw frame, horse, and hand-screw, the following tools will be indispensible, namely: a few brad awls of different sizes, or better still where it can be afforded, a hand-drill with half a dozen assorted drill points. The former will cost about five cents each, and the latter, drill-points and all complete, can be obtained for one dollar. Fig. 11, shows the hand-drill with point attached, also wrench for taking out, and screwing in drill-points. A few rat tail files will be found

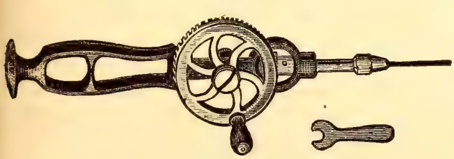

Fig. 11.

very useful in smoothing up the edges of quick curves. A flat file and a couple of three sided files will also be found of great service in finishing up the work after it has left the saw. The files of course, will require to be of different sizes. A tenon saw which will cost about seventy-five cents will often be wanted to cut the stuff near to the size required, and also to cut mitres and straight work where it is outside the pattern. A light claw hammer, a glue pot, and an assortment of small brads will also be found very useful. A piece of cork two inches wide, one inch thick, and three inches long, makes the best rubber known; wrap the sandpaper round it, then smooth up your work and it will be found that the cork will not permit the sandpaper to cut off the sharp angles of the work. Where the cork can not be obtained, a good substitute can be made by taking a piece of flat India rubber and gluing it on to a piece of pine board. When using, keep the rubber side next to the work. It will also be well to have a good supply of saws of all sorts on hand, for the beginner *will* break a number of them before accomplishing much work; but this should not be cause for discouragement, for we venture to say, that no one has reached to any degree of perfection in the art of scroll-sawing, without breaking a large number of saws; with care and practice however, saws can be made to last a long time, and the longer they last, the smoother and cleaner they cut.

Lessons in Magic.—VIII.

The Filtration.

THIS trick is so old, that it will appear as new to most of the present generation, very few of whom have ever seen it. It is a most excellent illusion, and may be exhibited with equal effect in the drawing-room or on the stage.

Two large glass jars, one filled with water and the other with ink, are brought on the stage and placed at a distance from each other. To convince the audience that there is really ink in one, the performer ladles out some and pours it on a piece of white paper which is immediately discolored.

All doubts as to the contents of the jars being satisfied, they are covered with handkerchiefs, and on removing these, it

is found that the jar which contained the ink now holds the water, whilst that which held the water is filled with ink.

For this trick all that is needed is a small packet of good ink-powder and a black silk lining which fits exactly inside one of the vases, and to which is attached a thread. The silk lining is placed inside one of the vases which is then filled with water, and the thread attached to the lining is brought over the side of the vase, so as to be readily accessible to the hand; in this shape it appears as if the vase was really filled with ink, and to complete the illusion a small wooden spoon, the handle of which is hollow and filled with ink. is apparently dipped into the vase and its contents being immediately afterward poured on to a sheet of paper—unsized paper is best, as it absorbs the ink quicker and becomes black much sooner than a sized article—the audience are convinced that it is really a vase of ink that they see. The other vase is filled with pure water. To effect the change the two vases are covered with cloths of any kind, and in removing that which is over the supposed ink, the lining is lifted out by means of the thread, and there appears a jar of clear water, whilst the other jar which held the water is now filled with ink, and a very good article at that, for in covering it, you managed to drop the contents of the packet of ink-powder into the water.

The foregoing trick originated in this way; many years ago there appeared in Paris a conjurer named Phillippe who astonished the whole city by his wonderful tricks. He did many clever things, and amongst others produced a number of large glass bowls filled with water and gold-fish from a lady's shawl. This trick being entirely new, attracted large audiences, so his competitors set their wits to work to discover how the thing was done. This they did not succeed in at the time, but one of them hit on the trick I have just explained, and by it managed for a while to share with Phillippe the patronage he had so long monopolized.

More modern conjurers have combined the two tricks, altering them however both in the manner of performing and the effect, but before proceeding I will explain Phillippe's trick of

The Fish Vases as now Performed.—The "vases" are small round glass bowls of about six inches in diameter, and furnished with rubber caps or covers, which fit tightly on and are retained in their places by the "lip" of the bowl. When about to exhibit the trick, the "vases" are filled with water and gold-fish, the rubber caps put on, and one each of the bowls is placed either in the breast pockets of the performer's coat or waist-coat, or else in large oil-silk bags or pockets, which he wears under his coat.

Instead of a shawl, several large silk handkerchiefs are used. The performer takes one, rolls it into a wad, throws it in the air and tramples it under foot to show that it is empty; then taking it by two of the corners with the tips of his fingers, he brings it over his left arm, letting it fall in such way as to entirely veil his breast and the action of his right hand; whilst in this position that hand searches for and grasps one of the bowls which it brings immediately under the centre of the handkerchief; the left hand is now brought into play to withdraw the handkerchief, and in doing this, it at the same time pulls off the rubber cover which is kept concealed in the handkerchief. The bowl of fish and water is advanced to the audience by the right hand, whilst the left throws the handkerchief and cover on the stage.

These motions are repeated with a variation of the hands, as many times as are necessary to bring out all the bowls of water, a fresh handkerchief being used for each bowl. At the conclusion of the performance the trick of

The Fish Vases and The Filtration Combined may be very readily introduced, as follows: A large glass jar, shaped like a goblet, the base of which is made either of wood, metal or silvered glass, is brought on to the stage, filled to the brim with ink, and given to an assistant to hold.

The performer then picks up one of the bowls of water which he has just brought out of a handkerchief, and re-covering it with another handkerchief, he suddenly throws it into the air, when to the aston-

ishment of all, the handkerchief proves to be empty; the attention of the audience is now directed to the jar of ink, which the assistant has been holding, and although uncovered and not out of sight, the ink has gone, and in its place is pure water.

For this trick the performer requires a bowl, and also a jar of peculiar coustruction. The bowl is made with a piece of glass fitting entirely across its mouth, but at a little distance—say about the eighth of an inch—below the top edge; a hole is then drilled in the bottom, and through this hole the bowl is filled with water and then corked; a little water is poured on to the top of the plate which goes across the mouth, and as this is accidentally (?) spilled in lifting up the bowl, the spectators are impressed with the idea that they see an ordinary bowl filled with water. The handkerchief which is used has a ring of wire about the size of the bowl, sewed to one side of it.

When the performer picks up the handkerchief, he veils his breast with it, in the same manner as when taking out the bowls, but this time puts *into* his pocket the glass jar which is in his right hand; then passing that hand under the handkerchief, he causes its folds to fall in such a way about the wire ring which is fastened inside, as to give an impression from the shape that the bowl is still inside. When the time comes for the disappearance, the handkerchief is tossed into the air, caught as it is falling, and shaken so as to show that it is empty.

The jar which holds the ink is double, or may be more easily arranged by fitting two jars one inside of the other; between these sides is a black silk lining which is attached to a coiled spring in the base of the jar. There is a button on the outside of the jar-base which controls this spring. When the performer commands the jar to "change!" the assistant pushes the button, the spring is released, and the lining flies into the base, revealing the pure water in the jar.

—A model of New York harbor, with real water and miniature shipping, is on exhibition in Boston.

Engraving on Wood—IV.

BY SARAH E. FULLER.

IN our last paper we described the way in which to cut the picture of flowers and leaves. We will now give you some instruction that was anticipated somewhat by our last lesson. If you have tried to cut the picture, you will understand the lesson we now give you.

The first thing to learn, is how to hold the tools. Hold the handle of the tool, with the second, third and fourth fingers of, and the palm of the right hand, grasping firmly, and with precision, but yet lightly, and use the forefinger to guide the tool. In cutting small pictures, let the thumb be pressed against the side of the block, as shown in Fig. 13.

At no time, should the tool be held or pinched between the forefinger and thumb; the forefinger always guides the tool, and the thumb acts as a rest, the other fingers and palm holding and moving the tool as required. By attending to these points in the beginning, you will acquire the habit of working with freedom, and yet with a precision, which will be impossible to gain, if you do not hold the tools properly.

When the blocks are large, the thumb rests on the face of the block, as shown in Fig. 14.

The tool held as we have told you, plays forwards and backwards against the thumb, which rests steadily, while the tool is cutting, but moves whenever, and as fast as is required. It generally takes considerable time to get the habit of holding the tools correctly. It is sometimes useful practice to hold a tool, and go through the motions of cutting, without a block. One needs suppleness of the fingers, and delicacy of touch, which may be promoted by this exercise.

For a regular course of lessons in engraving, the first lessons are in cutting tints. By tints we mean those portions of engravings that are made with a series of regular lines without having cross lines.

For a first trial, choose a small piece of wood; an inch or so square will answer. Prepare the wood as we instructed in a

former number; pumice it carefully, so as to leave no scratches, and whiten it lightly. When quite dry, rule lightly with a fine pencil, some "guide" lines, from the top to the bottom about quarter of an inch apart.

Place the block on your sand bag cushion described in March number, and all your apparatus adjusted as there directed. Hold the block with your left hand firmly to prevent it slipping, but so that you can readily move and turn the block as required while engraving. The left hand performs a very essential service in making engravings.

Select a tool of medium grade for the first lesson, holding the tool and adjusting the block as described; commence near the upper edge, and just on the right side; guide the tool with the forefinger, and cut slowly, and not too deeply, a line straight as possible across the block. It would be well to cut this first line, just below the pencil "guide line," at the top of your block. Keep the same pressure of tool into the wood throughout the entire length of line. Having determined what width of line, or "face" you will leave, when you commence the second line, place the tool at the required distance below your first cut, and cutting into the wood the same depth as before, guide the tool slowly across the block, endeavoring to leave the line as wide throughout its entire length as at its beginning.

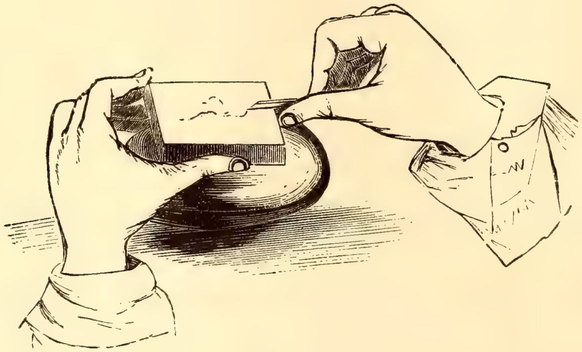

Fig. 13.

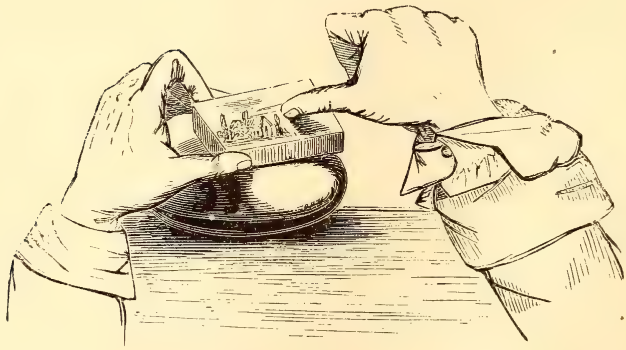

Fig. 14.

The line that is between your two cuts is the first line of your tint, for the lines that are left are the lines that receive the ink in printing, and the straight cuts appear white. The quality of plain tint de-

pends upon the evenness of the lines which make it, both the black lines, and the white cuts. The color or tone depends upon the width of these lines and cuts.

If possible to cut the second line without either swerving upwards, making the line thinner, or downwards making it thicker than at its commencement, a great success has been achieved by our student. commence every line carefully, and proceed slowly, observing closely with the eye the width of the lines left, and with the fingers the depth of the cuts. You

Fig. 15.

will now understand why you were instructed to hold the tools so carefully, for to know at what depth you are making the cuts, requires great delicacy of touch, which you will perceive more and more as you proceed. Do not think about the time required to cut a line ; let each line for the time being be the most important matter in the world, and proceed as carefully as if you expected to receive hundreds of dollars for the beauty and precision of your first tint block. The "guide lines" in pencil will enable you to observe whether you are cutting your lines straight, but if, unfortunately, the lines get to swerving up or down, do not continue in the wrong direction. Stop, and take the tool out of the cut, and put it into the wood a little further along, and observing its distance from the nearest guide line, commence again. It is better to have stops in the tint than crooked lines. It will take quite considerable time to get accustomed to the use of tools, so that it will be possible to cut an even tint; but patience and perseverance will be re warded with success.

Collecting and Pressing Seaweeds—I.

THE study and collecting of seaweeds (algæ) is a delightful recreation, particularly during the summer months, when so many are spending their vacation on the seashore, and are at times lost for something to do.

The seaweeds of our coast are in their greatest beauty and variety during our hot summer months. A tide table, or a friendly and communicative fisherman, is indispensable for reference, as by consulting either of these you can always be sure of striking the particular part of the coast at just the beginning of ebb tide, which will give you a chance to collect all the way down to extreme low tide, and then as the water returns laden with a rich harvest of "drift," time and opportunity is at hand for a rich haul. In this way a locality can be thoroughly worked. To save time, and take full advantage of the ebb and flood of the tide, do not stop to wash the specimens carefully, but pack them in your basket compactly together, always remembering to keep the temperature outside and inside the basket as low as possible, or the mass of seaweeds will become heated, and fermentation will take place, which will utterly destroy every specimen. The surest means that I know of for protecting the specimens from the action of heat is to have a large thick towel or blanket loosely laid inside the basket, extra pieces of blanketing or towels to cover over the top surface of the seaweeds, and to go around the outside and bottom of the basket. These outside wrappings are to be fastened on the basket with string previous to starting home.

When on your ground collecting, always keep the basket sunk in some quiet and shady tide pool; as you collect the specimens take them to the basket and place them in it in layers. Rocky and sandy shores are always the best and cleanest locations to collect from; old docks built up on spiles are always great hiding places for the more delicate kinds of algæ that delight in shady cool locations, and the action of gliding water. Always try to be on your collecting ground at the

spring tides, consult your almanac for the times of new and full moon, and cultivate your friendly fisherman with a cigar or paper of tobacco, and politeness, which costs you nothing, but is always appreciated by these salty and very honest people. As a rule they are shy and reticent towards city folks, but when they know you they are always ready and pleased to post you as to particular locations on the coast where desirable specimens may be obtained in abundance. Or where the tide has cut into the land, thus forming "dykes" and "overlopes." During the spring tides these "dykes" are always desirable places for the seaweeds of quiet habit. Always after the heavy gales and spring tides there will be found on the high water line of our coasts, piled up in masses, immense quantities of seaweeds in the form of drift. This should be gone over carefully and will be found to be rich in deep sea specimens.

There are various methods of preserving seaweeds, and the best of them all consists in mounting them on paper. After having reached home with your specimens, it is necessary to begin preparing them for the press immediately as seaweeds soon spoil after their removal from their native element. The red weeds must be taken in hand first, as they begin to decay quicker than the other varities on account of containing a large percentage of gelatinous material (I have known them to *melt* away in two hours time after being out of water). Wash *all* your specimens in *clear salt* water that has previously stood some time to settle. By salt water I mean water taken from the ocean or river where the plants were collected. Fresh water will do if the salt cannot be obtained, but it has a decided tendency to change the colors of the seaweed, and also to rot them; still if the specimens are handled very quickly it will answer. For floating the specimens I have found a large meat dish (white) such as is used for serving large joints, to be the best. Fill such a dish with water, not up to the rim but as far as the shoulder or bend of the rim. Now immerse the paper under the water and place the specimen on top of it, allowing it to assume its natural habit of growth as near as is convenient for the size of the mounting paper. Now carefully and slowly lift out the plant on the paper, and lay it on a smooth board placed in a standing position so that the water will drain off. If parts of the plant become matted together, separate with a camel hair brush or sharp pointed stick. The spreading out of the finer parts of the plant can be accomplished very nicely by taking up a drop of water on the end of your finger and allowing it to fall on the part you desire to spread out.

Seaweeds can be dried with great success, and packed away for winter's entertainment, in the following manner. After having obtained your seaweeds, procure an old sheet, or piece of canvas which is to be staked to the ground with wooden pins cut from small branches of trees, (Fig. 1). These are hooked into holes that

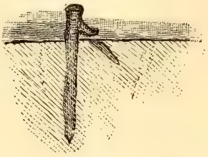

Fig. 1.

are perforated all along the edges of the sheet, and the long legs of the pins are driven into the earth. In this way the sheet is kept in position and spread out, all danger of the wind getting under it and scattering your specimens is avoided. On the sheet is spread a thin layer of *dry* and *clean sea sand*. As each specimen of seaweed is taken out of the water it is allowed to drip for a few moments, after which it is laid on the sand. The purpose of the sand is to rapidly carry off all moisture and disperse it by evaporation, and also to prevent the seaweed from sticking to the sheet. When the specimens are just so dry that they are pliable, *but not crisp*, place them in covered boxes to be kept till required for mounting. This drying must always be accomplished in the shade, as sunlight fades the colors, and the heat produces fermentation causing the gelatinous specimens to change into a pulpy mass.

In case clean fine sand is not attainable,

the specimens can be suspended on lines of strong thread stretched across some cool, dry, room that is free from dust.

For preserving the large coarse olive colored weeds with a view to studying their organs under the microscope, they should be immersed in pure glycerine, in which they will retain their natural color and form for several years.

One of the best portable presses that I know of consists of two bars of well seasoned oak or chestnut, with thumb screws at each end, and a few planed deal boards less than half an inch in thickness; these are varnished with black asphalt varnish. The board should be about eighteen inches long by about a foot broad. The screws should be well finished and at least six inches long, so that several pairs of boards can be pressed at once. These thin boards and a good supply of *clean* cotton or linen rags are all the apparatus necessary for field work.

The boards will be found very useful to lay the sheet of mounting paper on, holding it and the end of the seaweed firmly on the board with the left hand, under water in some quiet tide pool, using the right hand to adjust the specimen. After the seaweed is in position, the board can be stood up till the water has run off.

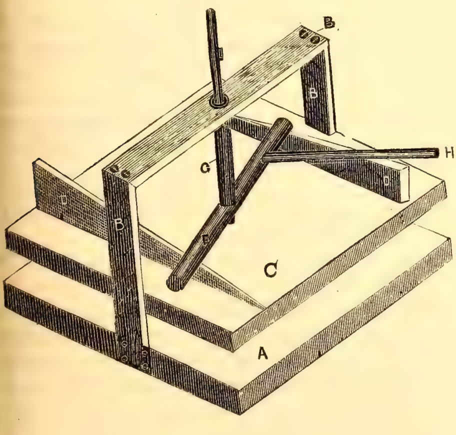

Fig. 2.

For indoor work a press is made as shown in Fig. 2. This press any amateur carpenter can easily construct, it being so simple. The bed A, consists of a stout board of oak or chestnut to which is screwed the framework, B, B, B; between these is a traveling top board, C, C, on the upper side of which are fastened with screws two inclined planes, D, D. The lever, F, travels on the inclined planes when moved by the handle, H, and can be prevented from sliding back by means of pegs inserted in the top edge of the planes, D, D. The traveling top board is kept close to the top of the frame, B, B, B, when not under pressure, by means of two elastic bands. It takes two days in hot weather for the specimens to dry, but in damp weather three, four, and even five, when the specimens are of a gelatinous nature.

When removing the rags great care must be taken not to tear the specimens from the paper. Always begin peeling the rag from the root or disc of the plant.

For mounting there is no better paper than Watman's best drawing paper, as it contains a large amount of sizing, causing the plants to adhere very firmly. For fancy mounting in groups for albums, English or French Bristol board is best.

Be careful in pressing the seaweeds not to put so much pressure that the seaweeds receive an embossed impression of the texture of the rag dryers. Never be in haste to take the specimens out of the press before they are thoroughly dry. Never attempt to hasten the drying by ironing with a hot iron, or placing them in a "slow oven," unless you wish to obtain some deplorable specimens of algology.

Editorial Notes.

Our New Offices.

WE write this in our new offices, at 14 Dey street, to which we have just moved. The new rooms are much more pleasant and convenient than our old offices, and when we get fairly settled we expect to remove many annoyances which cramped quarters entailed on us.

Our new offices are only a couple of doors from the main office of the Western Union Telegraph Company, and about

two minutes walk from the General Post Office, so that our location is central, and as we are only a block or so from a depot of the Metropolitan Elevated Railroad, we are quite accessible.

It may not be out of place to say that from the same office are issued the American Journal of Microscopy, and the American Reprint of the London Lancet.

The Heavens for June.

BY BERLIN H. WRIGHT.

Mercury will not be visible in June.

Venus will present a slightly gibbous phase throughout the month; that is, she will appear like the Moon a few days *after* First Quarter, or *before* Third or Last Quarter. She will be very close to Regulus, the brilliant star in the end of the handle of the Sickle, July 4, being about one degree north of the star. She will be in conjunction with the Moon June 23, being about 4° north. (In the May number, in the reference to the phases of Venus, read *semi-diameter* instead of *diameter*, in all except the first). Venus sets as follows:

June 10—10h. 24m. evening.
" 15—10h. 21m. "
" 20—10h. 18m. "
" 25—10h. 11m. "
" 30—10h. 5m. "
July 5—9h. 57m. "

Mars will be nearly 8° south of the Moon June 12, and on the 30th he will be in conjunction with the planet Saturn, passing so near him as to almost touch his northern limb. When nearest, Mars will be about one-sixtieth degree north of Saturn. Mars rises as follows:

June 5—1h. 10m. morning.
" 10—0h. 59m. "
" 15—0h. 47m. "
" 20—0h. 36m. "
" 25—0h. 24m. "
" 30—0h. 13m. "
July 5—0h. 2m. "

Jupiter becomes an evening star, June 2, being then 90° west of the Sun. He will be about 5° south of the Moon June 10, and stationary July 2. He rises as follows:

June 5—0h. 29m. morning.
" 10—0h. 9m. "
" 15—11h. 47m. evening.
" 20—11h. 28m. "
" 25—11h. 8m. "
" 30—10h. 49m. "
July 5—10h. 30m. "

The following eclipses, transits and occultations of his Satellites are visible in June:

Satellite I.	D.	H.	M.	
Eclipsed, begins	3	3	4	morning
Transit, begins	4	1	45	"
Transit (shad.,) ends	4	2	42	"
Transit ends,	4	4	4	"
Transit (shad.,) begins	11	2	16	"
Transit, begins	11	3	38	"
Occultation, ends	12	3	5	"
Transit (shad.,) begins	18	4	9	"
Eclipsed, begins	19	1	20	"
Transit (shad.,) ends	20	0	57	"
Transit, ends	20	2	17	"
Eclipsed, begins	26	3	15	"
Transit (shad.,) begins	27	0	31	"
Transit, begins	27	1	48	"
Transit (shad.,) ends	27	2	51	"
Transit, ends	27	4	7	"
Occultation, ends	28	1	16	"
Satellite II.				
Transit, ends	2	3	11	"
Transit, begins	9	2	54	"
Transit (shad.,) ends	9	3	4	"
Transit (shad.,) begins	16	2	45	"
Occultation, ends	18	3	21	"
Eclipsed, begins	25	0	26	"
Transit, ends	27	0	5	"
Satellite III.				
Eclipsed, ends	3	4	12	"
Transit, ends	14	3	52	"
Transit (shad.,) ends	20	2	27	"
Transit (shad.,) begins	27	2	48	"
Satellite IV.				
Occultation, begins	14	3	36	"
Transit (shad.,) begins	21	1	16	"
Occultation, ends, (July)	1	0	52	"

At the time of the occultation of Satellite IV. (June 14), the Satellites will occupy the following positions with respect to Jupiter:

Sat. I.—A little more than twice Jupiter's apparent diameter east, and moving from Jupiter.

Sat. II.—A little further west than Satellite I is east, and moving towards Jupiter.

Sat. III.—Upon Jupiter's disc, being in transit, and appearing 16 minutes after the occultation of Satellite IV begins.

Sat. IV.—Will disappear behind the planet at his western limb.

Saturn will be 8° south of the Moon June 13. His near approach to the planet Mars has already been mentioned. He will be 90° west of the Sun July 7, and after that date will be an evening star. June and July, 1879, are the two most favorable months of the year to observe the rings of Saturn. Saturn rises as follows:

June 5—1h. 48m. morning.
" 10—1h. 30m. "
" 15—1h. 10m. "
" 20—0h. 52m. "
" 25—0h. 33m. "

June 30—0h. 14m. morning.
July 5—11h. 51m. evening.

37m., north declination 36° 43'. By referring to a chart of the heavens, it will be seen to be one-

" 29—10h. 8m. evening.

THE GREAT NEBULA IN HERCULES.—This Nebula is known as 13 Messier; also as Halley's Nebula, having been discovered by Halley in 1714. It is situated in Right Ascension 16h. third of the way from *Eta* to *Zeta;* the two stars which constitute the west side of the quadrilateral in Hercules, situated on a line from Vega to the Northern Crown, and midway between them.

This nebula is visible to the naked eye more easily than the Great Nebula of Orion, described some time since. It is resolvable, and one of the most attractive objects of this class in the heavens. "Perhaps no one ever saw it for the first time without uttering a shout of wonder." Only the most powerful telescopes will entirely resolve this nebula, but a good three-inch glass will resolve the streamers, of which there are six projecting from either side.

Hercules is near the meridian at 9 o'clock in the evening, in June.

Penn Yan, N. Y.

BOOK NOTICES.

Plain Directions for the Construction and Erection of Lightning Rods. By John Phin, editor of the "Young Scientist," and the "American Journal of Microscopy," Third Edition, Enlarged and fully Illustrated. Cloth, 30 cents. New York; Industrial Publication Company.

The season is now approaching when the voice of the lightning rod man will be heard in the land, and thousands of dollars will be spent in putting up rods, three-fourths of which will probably be useless, for it is an unfortunate fact that the average peddler of lightning rods thinks more of the money that he gets than of the protection which he furnishes. Indeed, so common is it for lightning rods to be defective, that many persons have been led to entirely doubt their efficiency, and yet, no fact is more thoroughly established than that a good lightning rod affords perfect protection.

The work before us is the only one within our knowledge that has not been published for the

purpose of puffing some patent; it is short, simple, and fully illustrated, and the practical directions are so full, that any ordinary mechanic can, by following them, put up a really good rod. And it is a comforting assurance to be told that a really good rod need not infringe any patent, the best methods of construction being older than any patents now in force.

The New York Evening Express Almanac for 1879: Handbook of Politics, Statesman's Manual and Statistical Register for Bankers, Merchants and Agriculturists. Price 25 cents. New York: Office of *Evening Express.*

The range of subjects which the compilers of this almanac have compressed into its pages is something astonishing. We have here a goodly volume of nearly 400 large octavo pages filled with important statistics and general information. In addition to the usual matter found in all almanacs, it contains an enormous amount of general information in regard to the products, commerce, politics, geography, education, etc., of almost every country in the world, and all so arranged and condensed as to be easily available at a moment's notice. How all this can be done for 25 cents is one of the marvels of bookmaking.

Green Varnish.

There is a most beautiful transparent green varnish employed to give a fine glittering color to gilt or other decorated works. As the preparation of this varnish is very little known, an account of it may in all probability prove of interest to many of our readers. The process is as follows:—Grind a small quantity of a peculiar pigment, called "Chinese blue," along with about double the quantity of finely-powdered chromate of potash, and a sufficient quantity of copal varnish thinned with turpentine. The mixture requires the most elaborate grinding or incorporating of its ingredients, otherwise it will not be transparent, and therefore useless for the purpose for which it is intended. The "tone" of the color may be varied by an alteration in the proportion of the ingredients:—A preponderance of chromate of potash causes a yellowish shade in the green, as might have been expected, and *vice versa* with the blue under the same circumstances. This colored varnish will produce a very striking effect in japanned goods, paper-hangings, &c., and can be made at a very cheap rate.—*Cabinet-maker.*

Nickel Plating.

A foreign exchange gives the following recipe: To a solution of five to ten per cent. of chloride of zinc, as pure as possible, add sufficient sulphate of nickel to produce a strong green color, and bring to boiling in a porcelain vessel. The piece to be plated, which must be perfectly bright and free from grease, is introduced so that it touches the vessel as little as possible. Ebullition is continued from 30 to 60 minutes, water being added from time to time to replace that evaporated. During ebullition nickel is precipitated in the form of a white and brilliant coating. The boiling can be continued for hours without sensibly increasing the thickness of this coating. As soon as the object appears to be plated it is washed in water containing a little chalk in suspension, and then carefully dried. This coating may be scoured with chalk, and is very adherent. The chloride of zinc and also the sulphate of nickel used must be free from metals precipitable by iron. If during the precipitation the liquor becomes colorless, sulphate of nickel should be added. The spent liquor may be used again by exposing to the air until the contained iron is precipitated, filtering and adding the zinc and nickel salts above. Cobalt also may be deposited in the same manner.

Plaster of Paris.

Plaster of Paris may be made to set very quickly by mixing in warm water to which a little sulphate of potassium has been added. Plaster of Paris casts, soaked in melted paraffin, may be readily cut or turned in a lathe. They may be rendered very hard and tough by soaking them in glue-size until thoroughly saturated, and allowing them to dry. Casts of plaster of Paris may be made to imitate fine bronze by giving them two or three coats of shellac varnish, and when dry applying a coat of mastic varnish, and dusting on fine bronze powder when the mastic varnish becomes sticky. Rat-holes may be effectually stopped with broken glass and plaster of Paris. The best method of mixing plaster of Paris is to sprinkle it into water, using rather more water than is required for the batter; when the plaster settles pour off the surplus water, and stir carefully. Air bubbles are avoided in this way.—*Scientific American.*

Splitting Paper.

It is one of the most remarkable properties of that wonderful product, paper, that it can be split into two or even three parts, however thin the sheet. We have seen a leaf of the *Illustrated News* thus divided into three parts, or three thin leaves. One consisted of the surface on which the engravings are printed; another was the side containing the letter press, and a perfectly blank piece on each side was the paper that lay between. Many people who have not seen this done might think it impossible; yet it is not

only possible, but extremely easy, as we shall show.

Get a piece of plate glass and place on it a sheet of paper; then let the latter be thoroughly soaked. With care and a little dexterity the sheet can be split by the top surface being removed. But the best plan is to paste a piece of cloth or strong paper to each side of the sheet to be split. When dry, violently and without hesitation pull the two pieces asunder, when part of the sheet will be found to have adhered to one and part to the other. Soften the paste in water and the pieces can be easily removed from the cloth.

The process is generally demonstrated as a matter of curiosity, yet it can be utilized in various ways. If we want to paste in a scrap-book a newspaper article printed on both sides of the paper, and possess only one copy, it is very convenient to know how to detach the one side from the other. The paper when split, as may be imagined, is more transparent than it was before being subjected to the operation, and the printing ink is somewhat duller; otherwise the two pieces present the appearance of the original if again brought together.

Some time ago the information of how to do this splitting was advertised to be sold for a considerable sum. We now impart it to all our readers gratuitously.—*B. and O. Printer and Stationer.*

Practical Hints.

Cleaning Brass.—Finely rubbed bichromate of potash mixed with twice its bulk of sulphuric acid and an equal quantity of water, will clean the dirtiest brass very quickly.

Marine Glue.—The following recipe is said to give very good results: Dissolve one part of India-rubber in 12 parts of benzole, and to the solution add 20 parts of powdered shellac, heating the mixture *cautiously* over the fire. Apply with a brush. This is much used in the construction of galvanic batteries.

To Restore Spotted Varnish.—If the varnish has been blistered by heat or corroded by strong acids, the only remedy is to scrape or sandpaper the article and revarnish. Spots may often be removed by the following process: Make a mixture of equal parts of linseed-oil, alcohol, and turpentine, *slightly* moisten a rag with it, and rub the spots until they disappear. Then polish the spot with ordinary blotting paper. Varnish injured by heat can hardly be restored in any other way than by removing it and applying a fresh coat.

To Make Iron Take a Bright Polish Like Steel.—Pulverize and dissolve the following articles in one quart of hot water: Blue vitriol, one ounce; borax, one ounce; prussiate of potash, one ounce; charcoal, one ounce; salt, one half-pint; then add one gallon linseed oil. Mix well, bring your iron or steel to the proper heat and cool in the solution. It is said the manufacturers of a certain governor paid $100 for this recipe, the object being to case-harden iron so that it would take a bright polish like steel. We regard the process as one of questionable utility.

Cements.—To make cement for attaching labels to metals, take ten parts tragacanth mucilage, ten parts of honey, and one part flour. The flour appears to hasten the drying, and renders it less susceptible to damp. Another cement that will resist the damp still better, but will not adhere if the surface is greasy, is made by boiling together two parts shellac, one part borax, and sixteen parts water. Flour paste to which a certain proportion of nitric acid has been added, and heat applied, makes a lasting cement, but the acid often acts upon the metals. The acid converts the starch into dextrine.

Potassium.—The metallic appearance of potassium is usually exhibited by cutting a fresh surface which is immediately examined. But the surface becomes dim almost instantly. As a lecture experiment, Dr. Erckmann, introduces a piece of potassium, of the size of a pea, into a small test tube, heats to fusion, turns the glass round and round till the metal congeals, and then seals up the tube. The greater part of the potassium is deposited on the sides of the tube as a specular metallic coating, resembling silver, and can be exhibited during lectures, etc. The other alkaline metals may be similarly treated.

To Protect Iron from Rust.—Iron can be protected from rust and made very pleasing in color by a method invented by Mr. Dode. He coats the surface with a thin film of borate of lead, in which some oxide of copper has been dissolved, and some scales of precipitated platinum held in suspension, by means of a brush or a bath. He then heats the composition until it is diffused. The result is a thin, glassy coating, which will withstand the action of sewer gases, dilute acids or alkalies, and the heat of a kitchen fire. If all be true that is said of this "platinized iron," as it is called, it will find numerous applications.—*Kansas City Rev. of Sci. and Ind.*

Glue.—Carpenters should remember that fresh glue dries more readily than that which has been once or twice melted. Dry glue steeped in cold water absorbs different quantities of water according to the quality of the glue, while the proportion of the water so absorbed may be used as a test of the quality of the glue. From careful experiments with dry glue immersed for twenty-four hours in water at 60° Fah., and thereby transformed into a jelly, it was found that the finest ordinary glue, or that made from white bones, absorbs twelve times its weight of water in twenty-four hours; from dark bones, the glue absorbs nine times its weight of water; while the ordinary glue, made from animal refuse, absorbs but three to five times its weight of water.—*Building News.*

EXCHANGES.

A Smith & Wesson automatic ejector revolver, key check and stencil plate outfits, wanted for a combination saw, lathe, &c. Thos. D. Adams, Lock Box 61, Franklin, Pa.

J. T. Bell, Franklin, Pa., has brass condensing and exhausting air syringe, 100 good specimens (75 lbs) mostly silver ore, to exchange for gun, telescope, magic lantern, music box, or offers.

Wanted, back No.'s of the YOUNG SCIENTIST (for 1878), for a good dark lantern, cost $1.25. G. U. Bigelow, Palmyra, N. Y.

Duplicate collections of sea mosses from Oregon coast, for eye-glasses, back No.'s YOUNG SCIENTIST, or paper (working) pattern of best puzzle. Theo. Boone, Oneatta, Benton Co., Oregon.

Wanted, a microscope with accessories, in good condition, worth $5 or $10; state what is wanted in exchange. Will. H. Brewster, Middlebury, Vt.

Three vols. of Frank Leslie's Boys and Girls Weekly, cost $2.50 vol., to exchange 6 months for vol. 1 of YOUNG SCIENTIST, the rest for good books on electricity and science. Walter M. Brown, Owen Sound, Ont.. Canada.

Wanted, book, "Corner Cupboard or Facts for Everybody," in exchange for a card printer and type. H. E. Burnham, 176 Adams Ave. E., Detroit, Mich.

State what will be given for 250 foreign stamps, all different; list of other stamps sent on application. C. E. Chegwidden, 140th street, Mott Haven, N. Y.

Wanted, in exchange for good guitar, cost $25, a stationary engine, or bracket saw and turning lathe combined, or offers. Frankie Park, Dodge's Corners, Waukesha Co., Wis.

I have a magic lantern with 35 slides, cost $5; would like to exchange it for almost anything of similar value. Address all offers to C. Von Eiff, Box 4,465, City.

Fine carbine rifle, loads from muzzle or breech, in good condition; will exchange it for a double barrel shot gun, watch, or small rifle with bore 22-100. The Editor's Eye, 209 Rhodes Ave., Chicago, Ill.

Wanted, to exchange, North Carolina minerals, shells, stamps and Confederate money, for minerals, archæological specimens, Indian relics, vertebrate and invertebrate fossils, and curiosities for my museum. Robert H. Engle, Box 325, Raleigh, N. C.

Three volumes of Oliver Optic's (Wm. T. Adam's) works, Seek and Find, Fighting Joe, and The Yankee Middy, exchanged for cabinet mineral specimens. Anthony Garner, P. O. 53, Ashland, Pa.

To exchange, a seven shooting revolver of best make, in good condition, size of bore 22-100 in.; state what is offered in exchange. H. V. H., P. O. Box 47, Coeymans, Albany Co., N. Y.

Fairbank's No. 1 chemical scales and weights, cost $15, for a bracket saw with or without lathe attachment; scales warranted perfect; will give a *good* trade. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, double-barrel shot-gun or scroll saw, in exchange for telegraphic key and sounder on one base, Craig microscope, etc. C. H. Jordan, Shimersville, Lehigh Co., Pa.

Unmounted microscopic objects such as foraminifera, spicules, starches and parts of foreign insects, &c., to exchange for other mounted or unmounted objects. S. N. Hardy, Victoria, Cass Co., Neb.

A complete outfit for making chromo photographs and a small magic lantern and slides, worth $10, for a 5x7 printing press, or type, or a combination scroll saw and lathe. Geo. L. Lamson, La Fargeville, N. Y.

An oscillating steam engine, 1-inch bore, 2-inch stroke, to exchange for a household microscope, or offers. L. E. Kent, Santa Ana, Los Angelos Co., Cal.

Lippincott's, $4.00; Popular Science, $5.00; Phrenological, $2.00; Sanitarian, $3.00; Library, 3 copies $1.00 each; Housekeeper, $1.00; all monthlies, 1879, complete; Daily Sun, N. Y.; Star, Cincinnati, 1 year, $5.00; make offers. C. H. Kimball, Plymouth, N. H.

Wanted, correspondents to exchange insects with; will send full instructions for capture and make liberal exchanges. C. W. L., Box 3,565, N. Y. City.

Choice cabinet mineral specimens, for historical, scientific, masonic or other instructive books. C. A. Leeper, Bonanza City, Lemhi Co., Idaho.

To exchange, certificate for a course of lessons in shorthand writing, for books, or offers; also copies of the Student's Journal, for copies of YOUNG SCIENTIST; state what numbers you can furnish. H. C. Lucas, Macomb, Ill.

Wanted, all numbers of the YOUNG SCIENTIST for 1878, in exchange for the Story of a Bad Boy, or Chance for Himself; each cost $1.25. Jesse H. McIntire, Rockport, Mass.

Wanted, Queen's or McAllister's Household microscope; specimens of insects, woods, &c., in exchange; or state what is wanted. W. C. McNaul, Salina, Clinton Co., Pa.

Minerals, fossils, Indian relics and foreign stamps wanted, in exchange for same, or for greenhouse plants. Send list to Wm. J. Morgan, Somerville, N. J.

Wanted, a good wood lathe with attachments; state what is wanted in exchange, giving description of lathe. C. W. Munson, Nashville, Tenn.

Wanted, printing press, for a scroll saw and tools for finishing work. T. H. Nicholson, 14 East 127th St., N. Y. City.

To exchange, a novelty printing press, type and accessories, for a microscope with accessories, or minerals, or offers. T. W. Patterson, Warsaw, N. Y.

Wanted, a small printing press, Model or Novelty preferred, in exchange for a French microscope, objects and accessories, worth $20. C. L. Peticolas, 635 8th St. North, Richmond, Va.

Wanted, stereo camera with lens, ½ size view camera and lens, photo chemicals or offers, for rosewood writing desk inlaid with mother of pearl, and complete rosewood box of drawing instruments. A. B. Porter, 501 North Tenn. St., Indianapolis.

Wanted, a turning lathe from ½ to 2 inches swing; state what is wanted in return. Grant Price, Lock Box E, Cherokee, Crawford Co., Kan.

Wanted, a good set of engravers tools and a book of instruction, in exchange for an aquarium. H. E. Rhodes, Brighton, Iowa.

Wanted, to exchange, books for type; send specimen of printing of type; also state weight of font &c. J. Siler, 1,242 Broadway, St. Louis, Mo.

To exchange, a new book on fret sawing and wood carving, well illustrated and very handsomely bound, for good mineral specimens; also coins to exchange for minerals, &c. A. H. Spencer, East Clarendon, Vt.

Wanted, a good microscope or a pair of telephones, or other apparatus, in exchange for a photographic camera, lens, plate-holder, tripod, &c., valued at $5, entirely new, and enclosed in a neat case. Sheldon Sperry, 99 Lee Ave., Brooklyn, E. D., N. Y.

A collection of foreign and U. S. stamps, some paints and colored pencils, in exchange for Indian relics. Sherman Sweeting, South Butler, Wayne Co., N. Y.

A strong magnet, in exchange for Indian relics. Sherman Sweeting, South Butler, Wayne Co., N. Y.

The Young Scientist

SCIENCE IS KNOWLEDGE. — KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL FOR AMATEURS.

VOL. II. NEW YORK, JULY, 1879. No. 7.

How I Made my First Telescope.

BY W. B. HARRISON.

"HOW much we need a telescope to show us all these wonderful things," said our teacher to the class in Astronomy, at the close of a lesson, the subject of which was the planet Saturn.

"Where can we get one," timidly asked one of the scholars.

"I do not know," dreamily answered the teacher.

"Does a telescope cost much," asked another, and the same dreamy "'I don't know;' perhaps several hundred dollars," was the reply. The teacher then drew on the blackboard the form and combination of lenses of the common refracting telescope, closing with the remark that the principle of this telescope was very simple.

"Why couldn't we make one then," I suggested, warmed by the subject, but a sneer as the class took their seats, told me that I had ventured too far.

In the country school of New England, where this scene occurred, about thirty years ago, a half dozen of the larger scholars had formed a class in Astronomy and were using "Burritt's Geography of the Heavens" as a text book. They were plodding along somewhat blindly, with a teacher who knew but little of the science he tried to teach.

The sneer that greeted my suggestion, stung pretty deep, and at the same time aroused my ambition to possess a telescope. The diagram drawn by the teacher floated before my eyes. The more I thought of it, the more simple seemed the instrument. Where to get the lenses and fixtures was the trouble. By a careful reading of the Natural Philosophy we then used (Olmsted's Rudiments), I learned that only two lenses need be used for the telescope I wanted. The image formed at the focus of the larger lens, being magnified by a smaller lens placed behind this image. It was all very simple, surely.

I lay many, many evenings after this, looking at the stars through my bed-room window, and racking my brain how to get those lenses, for I was determined to have a telescope and to build it myself. In those days we had no YOUNG SCIENTIST to which we could refer for information, or to ask

where to get such things as telescope lenses. I made, what was to me, a desperate effort. I wrote to the editor of a New York paper, somewhat doubtful of a reply, asking him about the prices of lenses. A few days brought an answer and price list from an optician in Broadway. The prices were much lower than I expected, and I found that for about five dollars I could get two lenses, one of three inches diameter and three feet focus, and another of one inch diameter and one inch focus.

All through that spring and summer, I saved and hoarded pennies and shillings to purchase the coveted glasses. But to a boy of fifteen, in those days, especially when kept upon a farm, the opportunity to get money was limited. I dare not tell my project to any one, for if it were known that I intended to build a telescope, I would become a subject for ridicule. Telescopes were only made by expert mechanics, and at that time were only then used in colleges and similar learned institutions.

From spring to fall my little store of money increased, until I had enough saved to make the purchase. A man who kept a small store, near where I lived, was going to New York to buy goods. I told him my secret, gave him my money and the price list of lenses. In a few days he returned. My daily task being completed, in the evening I hastened to his house and obtained the coveted purchase. How my heart beat as I removed the last paper and the two glasses lay before me. I looked at them, turned them over, held them in my hands as they would be if placed in a tube, used them as eye glasses, etc., and after spending the entire evening looking through them, went to bed and slept with them under my pillow. In the morning I hid them in my trunk and spent the day contriving how to make the tubes.

I decided that paper would suit my purpose best, so I made a rough wooden cylinder a little more than three inches in diameter and a little more than three feet long. I turned this in a rude foot lathe I had made. I wrapped some thick paper around this cylinder and over this pasted three or four layers of paper, taking care to paste it smooth and even. When these were thoroughly dry, I put on three or four thicknesses of paper fastened with glue. Over this I pasted other layers, and when dry I found it made a light and strong tube. I painted the interior black with a mixture of lampblack and turpentine. I then made a tube about one inch long and small enough to go inside the large tube. I put this in my lathe, and with a sharp chisel cut it in halves, making two narrow rims or rings of it. One of these I put in one end of the large tube, about an inch from the end, and glued it there. I put in the lens, and then put in the other ring to hold it there, and glued it also. I fitted a paper cap over the end so as to protect the lens from dust or injury.

At the other end of the tube, a little more than three feet from the lens, I glued a piece of wood, turned to fit, and made a hole in it a little larger than my small lens. I made a small paper tube to fit this hole pretty tight, and fitted in the small lens and fastened it at one end in the same way that I had fastened the large lens. My instrument was now done, and I waited for evening to test its powers. That my heart beat quick when I raised it to take my first look at the heavens, is no exaggeration.

I found I could see quite well the hollows of the mountains in the moon, and could distinguish the shadows cast by the mountains. The crescent of Venus distinctly showed, and I could make observations on the satellites of Jupiter.

In using it for land objects, everything appeared inverted, but I soon got used to this, in fact I cared little for it, as I valued it most for astronomical observations.

I sadly wanted a stand for my telescope. I fastened a piece of wood about a foot long, lengthwise of the tube, and about midway from each end. Set in a groove that run lengthwise with the wood was a piece of brass about as thick as a card. It was fastened by screws put in crosswise through both wood and brass. That part of the brass that projected from the wood was nearly circular, about two and a half inches in diameter, with a hole through the centre. The top of an old fashioned

bed post about two feet long made the upright of my stand, and a cleft cut with a saw received the brass circle. A bolt passed through the upright and through the hole in the brass when they were put together. By tightening the nut to the bolt, I could hold the tube in position, yet it would tip up or down by using a little force. In the lower end of the upright, I bored a hole and drove in a piece of iron rod about three-eighths of an inch in diameter. A hole bored in the window sill received the projecting end of this rod. So far my stand answered very well. I could mount it at my window, tip the tube up or down and from side to side, and have a pretty fair view. But if I wished to move my instrument, I had no stand on which to place it. There was in my room an old fashioned round stand, with three feet to stand on the floor and an upright to which was attached the top. In this top or table I bored a hole to fit the rod, and put my telescope on the stand, the same as I had placed it on the window sill. I had now as good a stand as I could wish for.

In the evening, when making observations, I could place a candle upon the stand, and beside it I could have my books and papers. In this respect it was better than any stand I have since used.

It so happened that I never again attended the class in Astronomy, and the gratification which I expected to have when I could offer my telescope to the class, to view the wonders of the Heavens, I never realized. But when it became known that I really had made a telescope, I was beseiged with visitors to have a look through it, and when explaining the cost, and how I made the instrument, the expressions of surprise and wonder were more than sufficient to repay the pain caused by the sneers of the class, when I ventured to suggest that perhaps we could make a telescope.

Engraving on Wood—V.

BY SARAH E. FULLER.

HAVING cut the first block, place a small quantity of ink upon the slab, and, with the dabber, beat it until it is very fine. Then lightly beat the block, allowing the dabber to remain a few seconds at each beat. By carefully inking a cut, the exact quality of the engraving is perceived. In this first lesson, the character of the lines is shown very plainly. Some lines, probably, will be found thicker in one portion than in another; some will seem to have lumps on them, and some will have been cut too thin. If such is the case, it will not be possible to make this tint perfect, but with care it may be much improved. The lines that are too thin must be let alone; they cannot be mended. From the thick and lumpy lines, with a tool several degrees finer than the one with which the tint was cut, take off a slight shaving, now on the upper and now on the lower side, being careful not too take off too much, and so make the line too thin. When stops occur, turn the block downwards, and, with the same tool with which the tint was cut, re-enter the line, and cut the space of wood left, almost through to the end of the line

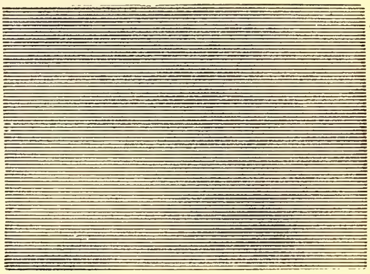

Fig. 16.

as it stopped. Then, with a fine tool, cut the remainder of the little stop of wood through on each side of the end of the lines, being careful not to make the ends of the lines too fine. When well done, the color of the tint will scarcely be disturbed by the meeting of the two series of lines; and it is always better to stop, and begin again, than to cut crooked lines.

And there will often be occasions when it will be necessary to unite tints, cut with different-sized tools, in this same manner. After trimming the lines of the tint as much as is necessary, ink the block again in the manner described, cut a piece of India proof paper, and lay it carefully

upon the block. With an ivory paper-knife, rub gently over the paper, pressing only sufficiently to make the ink adhere to the paper. Rub in the direction the lines are cut. Do this in all cases if possible. Light and delicate lines must be rubbed more gently than heavy lines; and, when printed, the press should be so adjusted that there will be less pressure upon them than upon the heavy lines. It is as it is technically called, than in the previous examples. After success is attained in producing plain tints, proceed with graduated tints, which are made by varying the width of the lines, and their distance from each other, as in Fig. 18. After facility is obtained in straight-line tints, proceed to the study of waved lines. Cut some lines which are slightly waved, as in Fig. 19. This kind of line will be

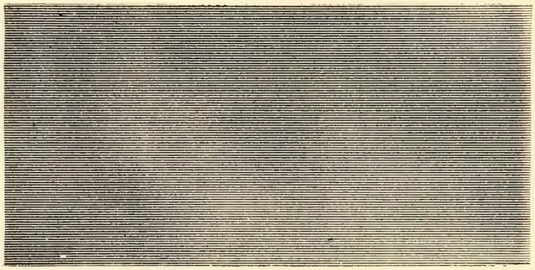

Fig. 17.

Fig. 18.

advisable to preserve proofs of work from the beginning, as they mark the progress of the individual, and they are always useful for reference.

For a second lesson, take a block (Fig. 16) somewhat larger than the first, and cut some similar tint. Proceed carefully, and be in earnest to make straight lines, and do not give up the practice till straight lines and an even tint are produced. The use of different-sized tools will give variety in the tint-studies. Also, with the same tool, cut lines with surface, and those that are sharp.

The next example, Fig. 17, is cut with a finer tool, and has more surface, or *face* found very useful in sky-tints. Afterwards cut some with more undulation of line, and some lines quite curved, as in Fig. 20. It should be observed, however, that it is not desirable to cut *masses* of tint with this line; for, "when the alternate undulations are much curved, the tint, when printed will appear as if intersected from top to bottom, like wicker-work, with perpendicular stakes." "This effect will be observable, both in lines cut by hand and by machine."

Examine fine examples of wood engraving, and observe closely the tints, and endeavor to imitate them; and continue the studies of tint-cutting till the pupil can

cut tints skilfully. Remember that future success depends upon the manner in which these first lessons are cut. When able to cut tints well, take a small picture which is made principally of tints. In a drawing on wood, the lines to express the given effects are cut according to the judgment of the engraver. In a transfer, all the lines are transferred to the wood just as they are to be cut. Hence transfers, at this stage of the pupil's progress, are most serviceable for practice.

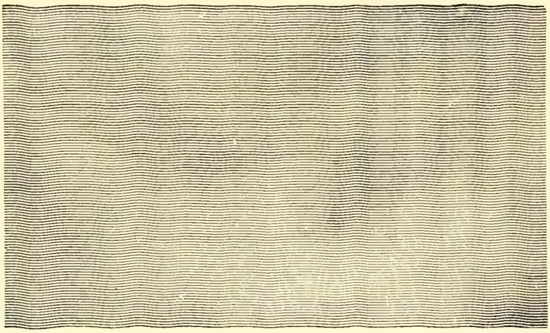

Fig. 19.

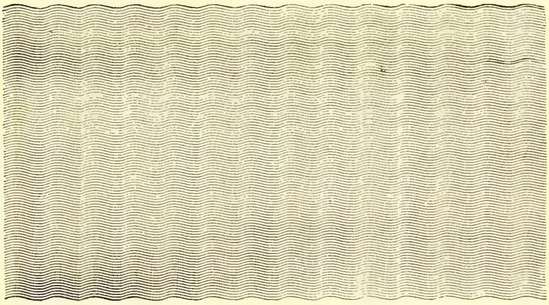

Fig. 20.

Scroll Sawing—III.

BY F. T. HODGSON.

By an examination of Fig. 12, it will be seen how saws are graded for sizes; they can be bought for about ten cents a dozen for the cheaper sort, and from twenty to thirty cents a dozen for the best qualities.

In choosing saw-blades, it is best to take only those that have sharp and regularly cut teeth. No.'s 0, 00, and 000, are very small and fine, and are used only for the finest of work, such as inlaying, cutting the veins of leaves, or turning small circles. The saws numbering from one to six are the best sizes for general work, as the smallest can be used for nearly all purposes of fine work, and the largest is strong enough for any work the amateur will care to undertake with a saw operated by hand. The finest saw blades have teeth so fine that they are scarcely visible to the eye, and make a cut or "kerf" so narrow that a slip of the paper of this book would fill it; they require no set, and are never sharpened, and can be used until they get broken, which is their natural end. For hand sawing the numbers 0 and 1 are the best sizes to use, unless very delicate work is required, when the finer numbers may be employed.

As before stated, the capacity of the

hand saw is limited, its work is slow and tedious compared with the foot-power machine, and the more delicate kinds of work, such as inlaying and mosaic, can not be done with it satisfactorily; yet, there is much in the hand frame besides

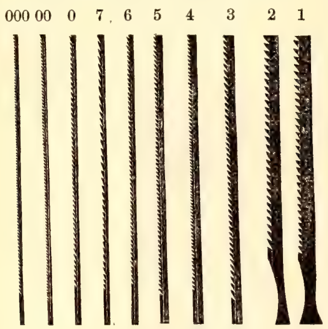

Fig. 12.

its cheapness, that will always recommend it as a good tool for boys to begin with.

There can be no question, where a foot-power machine can be afforded, but that it is the best; and that there are degrees of perfectness in treadle saws, is as true as that there are differences in hand-frame saws; and a bad, loose jointed, ramshakle foot machine, should above all things be avoided, for they are sure to lead to disappointment and loss of time, material and temper.

There are many machines in the market, good and cheap, capable, in good hands, of doing the finest of work; and a little judgment employed in the selection when about to purchase, will save a great deal of trouble and annoyance afterwards. If you have not set your mind on obtaining some particular make, or had some saw recommended by a friend in whom you have confidence, it would be well to send to the different dealers for circulars, and thereby make yourself acquainted with the worth and capabilities of each make before buying, always bearing in mind that a saw for which a small sum of money is paid, may turn out to be a very dear one in the end. However, if you purchase from any of the noted makers, you may rest satisfied that you have got the worth of your money.

Having procured your saw, the next thing is to use it, and here let me say, that in fret-sawing, like everything else of use, there is no royal road to perfection; it will be necessary for you to proceed step by step. You must not expect to cut elaborate brackets or intricate leaf work, on the very day you get the saw. In order, however, to lead you on as rapidly as possible to a point where results can reasonably be expected, I purpose to give you a few hints accompanied by the necessary illustrations; but before doing so, it will not be out of place to say a few words regarding the material which will be necessary to use in the initiatory exercises about to be gone into. As satisfactory results are not expected from these first beginnings, it would be foolish to waste expensive materials while practicing; therefore, the operator should lay in a supply of empty cigar boxes, which should be taken apart, and all the nails carefully withdrawn; the pieces should then all be laid together and a weight placed on the top to keep them from warping. The wood in these boxes, which is Spanish cedar, is excellent for the amateur to begin sawing with, as it is soft and easily worked. The paper can be taken off by soaking the pieces in water a few minutes, and then scraping them, after which the wood should be placed on end to dry, which it will do without warping. When the wood is dry, it should be rubbed with fine sandpaper, after which it is ready to receive a design for the first attempt.

Mark, with a lead pencil, on one of the prepared pieces of wood, lines as shown in Fig. 13, commencing with the saw at A, running down to the intersection, then changing the direction of the saw so that

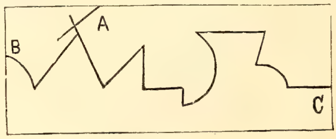

Fig. 13.

it cuts the line as far as the angular point, then change direction again and follow the line cutting out at B. Begin again at A, and follow the lines closely until the saw cuts through at C. Be sure and have all the angles sharp and well defined; for

in fret-work, nothing looks worse to the trained eye than the points of angles nipped off, or left ragged and slovenly done. Repeat this operation at least a dozen times, or until you can saw one that has all the angles and corners clear and bold. When this is accomplished, then attempt the cutting of Fig. 14, which is a little

Fig. 14.

more difficult. To cut this, start the saw at A, then run up to the point and a little further, then turn the piece around so that the saw will *take* at the point without spoiling the sharpness of the angle. The other points will require the same treatment, until B is reached.

Fig. 15 will perhaps be found more difficult at first to cut, than the two previous examples; for it is a curious fact, that straight lines are more difficult to follow

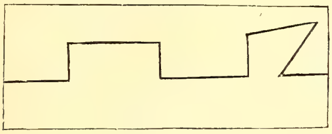

Fig. 15.

by the beginner than curved ones; the learner, however, should make it a point not to lay this example aside, until he can follow the lines exactly and leave all the angles sharp and clear.

Fig. 16 shows a series of curves, which may be next undertaken. This example

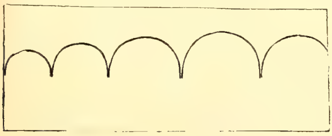

Fig. 16.

presents no particular difficulty; the junction of the curves will require a little care in getting them clear, sharp, and uniform.

Lessons in Magic.—IX.

Fresh Laid Eggs.

THE conjurer orders his assistant to bring a plate, which being done, he bids him hold it, and then approaching, taps him gently on the head; immediately he opens his mouth and there appears an egg.

The performer takes this out of his mouth, puts it on the plate, and then passing behind him, goes to his other side, taps him again on the head, and another egg appears. So he continues until he has six or more eggs, which he then prepares to hatch.

Before proceeding further, however, I will explain how the eggs are produced.

When the assistant goes for the plate, he puts an egg in his mouth and keeps it concealed there; the performer holds another egg palmed in his left hand. With his right hand he taps his assistant on the crown, who then allows the egg to appear at his mouth, and when the performer puts his left hand up to take it, it is drawn into the mouth again, whilst the one in the performer's hand is shown to the audience, who suppose it has just been taken from the mouth. This egg is laid on the plate, which the assistant holds, and as the performer passes behind him to cross to his other side, he takes a second egg from under his waistcoat and conceals it in his palm, as he did the first.

In this way he can take out as many as he wants. The last one, however, the assistant lets drop from his mouth on to the plate, and by this movement sets at rest any suspicion that the audience might have that the eggs did not come from his mouth.

The Patent Incubator.

"Now that I have these eggs, ladies and gentlemen," the conjurer says, "I will show you another very wonderful trick, which is no less than my patented method of hatching chickens. I will need, however, to borrow four or five finger-rings from the ladies, which my assistant will try to collect."

The assistant goes amongst the audience and requests those ladies who will favor him with their rings, to place them on a

piece of brass wire, about two feet long, which he holds by one end in his right hand. The object of this wire, he explains, is, so that he may not be suspected of changing the rings. Having borrowed three or four, he returns to the stage and hands the wire to the performer, who counts them aloud, "One, two; ah, I see that is an engagement ring, with a solitaire diamond; really, I ought to be very proud, Miss, at being so favored. Three; a plain gold, wedding ring. Four; well, number four may be gold, but I must say it looks very suspicious. However, I will return only what I receive."

He next takes a pistol with a large barrel and places the rings, one after another, in it.

"Number four, seems a trifle too large, to go in here," he says, "but as I doubt it's being gold, I will have no hesitation in shaping it so as to fit."

As he says this, he takes a hammer and batters the ring until it is flat, when he puts it into the pistol.

The pistol, he puts where it can be seen by all, and then brings out a deep saucepan, which he allows every one to examine.

Into this pan he puts four of the eggs which are on the plate, and then pouring spirits on them, sets it on fire.

"This is the way," he says, "that they cook eggs in Japan, I am told, but at any rate 'tis the way I cook in my pan. Quick, bring me the cover."

The assistant brings the lid; the saucepan is covered, handed to the assistant, and the performer, seizing the pistol, fires it at the pan. Bang! it goes; the cover is removed from the pan, and instead of the eggs there are four doves, each bearing a ring tied to its neck by a ribbon. The doves are carried to the owners of the rings, who are allowed to cut the ribbons from their necks, so that the rings can not in any way be changed.

For this trick, is needed four brass rings, four eggs which have been "blown," that is, their contents extracted by means of a little hole at each end; and a pistol, and a saucepan of peculiar construction.

The pistol is made with a small, narrow barrel, into which the powder and wad are put, and on top of this barrel is another and larger one, not connected in any way with the stock. It is in this, that the rings are put, but from the other that the charge is fired, though of course the audience must not be allowed to suspect this.

The saucepan is double; that is, there is one pan fitting into another, the inside one, however, having no handle. The lid fits into this inside one, and it is in this that the doves are placed by the assistant.

The rings are changed by the assistant, as he passes back to the stage, after collecting them, by merely letting those that are on the wire drop into his left hand, whilst brass ones to take their place, are dropped on to the wire from his right hand. This trick always pleases the ladies.

It sometimes happens that when a party of friends get together, the amateur conjurer is called upon to show some of his tricks, and on such an occasion, being entirely unprepared, he is at a loss what to do. In such an event, he has to depend entirely upon his manual dexterity, and press into his service such articles as are most readily obtained. If any of my readers are ever caught in this fashion, I would suggest as a suitable trick, that of

Telling the Court Cards by the Touch.

This little trick is only suitable for a small party, and according to the old-fashioned method, could only be performed before a party seated at table.

You inform the company that you propose to pick out the court cards by merely feeling them; that you will allow your eyes to be blindfolded, and that there may not be any suspicion of an arrangement of the pack, it may be thoroughly shuffled.

A handkerchief is accordingly placed on your eyes, and you proceed to do just what you promised, which is no very difficult matter, as your opposite neighbor, by a previous agreement made with you, presses your foot with his, when you come to the court cards.

But that trick is old, and the chances are, that if there be twenty persons present, fifteen will know how it is done, and then will follow any amount of "chaff" at the expense of the performer and his assistant.

But there is another way of doing the trick, which is not generally known, and appears quite incomprehensible.

Begin the trick in the old way, by having some arrangement with one of the parties present, who is, we will suppose, to cough, or give some other sign the moment you arrive at the cards you want.

Make as much flourish as possible, in showing the trick, and the probability is, that before you have been at it many moments, the company will begin to understand the means you employ. Then will follow laughter, probably a sneer. Notice none of these, but suggest that "some of you may have seen this trick before, but my manner of doing it is entirely new."

"Very new," some ill-natured fellow will say, "why, that is the identical method practiced by Noah for sorting the cards before placing them in the Ark. Do you suppose that we are all so dumb that we can't understand that most painful cough of our friend Makeshift?"

The company will of course smile at this; if rude, they may laugh, and some will advise you to learn some newer trick.

Their triumph, however, is but short lived, for turning toward them with a half reproachful air, and draping yourself majestically in the folds of your coat, you thus address them:—

"Gentlemen, I am sorry to find that you think so meanly of my magical acquirements as to suppose I would impose upon you by such a miserable trick. As the best means, however, of controverting your opinion and proving to you how you have wronged me, I will mount a chair in the middle of the room. First of all, examine the pack and shuffle it well."

And then to their great astonishment, you place the pack behind your back, and in a few moments sort out all the court cards.

In order to do this, the cards must have been previously prepared as follows: Taking the court cards, you run the point of a knife along the edge of the card, first at one end and then at the other—mind, not on the face, nor the back, but the edge. This will make a furrow, which can be easily felt by the fingers. When you take hold of the cards, you pretend to feel the centre with the thumb and fore-finger, but allow the tip of the little finger to come to the edge, and you will have no difficulty in discovering the cards. The furrow is so trifling that even when closely examined, it will not be noticed, especially if the pack be an old one. While doing the trick, hand the pack every little while to be shuffled, as that tends to lull suspicion.

Coloring and Finishing Brass-Work.

To prevent the every-day rusting of brass goods, the trade has long resorted to means for protecting the surface from the action of the atmosphere, the first plan of which is to force a change to take place. Thus, if brass is left in damp sand, it acquires a beautiful brown color, which, when polished with a dry brush, remains permanent and requires no cleaning. It is also possible to impart a green and light coating of verdigris on the surface of the brass by means of dilute acids, allowed to dry spontaneously. The antique appearance thus given is very pleasing, and more or less permanent. But it is not always possible to wait for goods so long as such processes require, and hence more speedy methods became necessary, many of which had to be further protected by a coat of varnish. Before bronzing, however, all the requisite fitting is finished and the brass annealed, pickled in old or dilute nitric acid, till the scales can be removed from the surface, scoured with sand and water, and dried. Bronzing is then performed according to the color desired; for although the word means a brown color, being taken from the Italian "*bronzino,*" signifying burnt brown, yet in commercial language it includes all colors.

Browns of all shades are obtained by immersion in solutions of nitrate or the perchloride of iron; the strength of the solutions determining the depth of the color. Violets are produced by dipping in a solution of chloride of antimony. Chocolate is obtained by burning on the surface of the brass moist red oxide of iron, and polished with a very small quantity of black lead.

Olive-green results from making the surface black by means of a solution of iron and arsenic in muriatic acid, polishing with a black lead brush, and coating it, when warm, with a lacquer composed of one part lac varnish, four of turmeric, and one of gamboge.

A steel-gray color is deposited on brass from a dilute boiling solution of chloride of arsenic; and a blue by careful treatment with strong hydrosulphite of soda.

Black is much used for optical brass work, and is obtained by coating the brass with a solution of platinum, or with chloride of gold mixed with nitrate of tin. The Japanese bronze their brass by boiling it in a solution of sulphate of copper, alum and verdigris.

Success in the art of bronzing greatly depends on circumstances, such as the temperature of the alloy or of the solution, the proportions of the metals used in forming the alloy, and the quality of the materials. The moment at which to withdraw the goods, the drying of them, and a hundred little items of care and manipulation, require attention which experience alone can impart.

To avoid giving any artificial color to brass, and yet to preserve it from becoming tarnished, it is usual to cover properly cleaned brass with a varnish called "lacquer." To prepare the brass for this, the goods, after being annealed, pickled, scoured and washed, as already explained, are either dipped for an instant in pure commercial nitrous acid, washed in clean water, and dried in sawdust, or immersed in a mixture of one part of nitric acid with four of water, till a white curd covers the surface, at which moment the goods are withdrawn, washed in clean water, and dried in sawdust. In the first case the brass will be bright; in the latter, a dead flat which is usually relieved by burnishing the prominent parts. Then the goods are dipped for an instant in commercial nitric acid, and well washed in water containing some ,argol (to preserve the color till lacquered), and dried in warm sawdust. So prepared, the goods are conveyed to the lacquer room, where they are heated on a hot plate and varnished.

The varnish used is one of spirit, consisting, in its simple form, of one ounce of shellac dissolved in one pint of alcohol. To this simple varnish are added such coloring substances as red sanders, dragon's-blood, and annatto, for imparting richness of color. To lower the tone of color. turmeric, gamboge, saffron, Cape aloes, and sandarac are used. The first group reddens, the second yellows the varnish, while a mixture of the two gives a pleasing orange.

A good pale lacquer consists of three parts of Cape aloes and one of turmeric to one of simple lac varnish. A full yellow contains four of turmeric and one of annatto to one of lac varnish. A gold lacquer, four of dragon's-blood and one of turmeric to one of lac varnish. A red, thirty-two parts of annatto and eight of dragon's-blood to one of lac varnish.

Lacquers suffer a chemical change by heat and light, and must therefore, be kept in a cool place and in dark vessels. The pans in use are either of glass or earthenware, and the brushes of camel's-hair with no metal fittings,—*Ironmonger's Review.*

The Heavens for July.

BY BERLIN H. WRIGHT.

MERCURY will be brightest July 24-27, being an evening star and setting as follows:

July 20—8h. 40m. evening.
" 25—8h. 31m. "
" 30—8h. 17m. "

This will not be a favorable opportunity to observe this planet, owing to its slight altitude at sunset, and the long duration of twilight.

VENUS will be very close to Uranus July 8, in the evening, being about one-fourth of a degree south of him. She will be at greatest eastern elongation July 16, being at that time 45° 33′ east of the sun, and having a half-moon phase. She will be 4° north of the moon July 22, at the time of setting. Venus is moving eastward past the stars, passing from the eastern part of Cancer to the eastern part of Leo in July. On the 5th of July she will cross the handle of the Sickle in Leo, being but one-half degree north of *A* Leonis (Regulus). Venus sets as follows:

July 5—9h. 57m. evening.
" 15—9h. 38m. "
" 25—9h. 16m. "

MARS will be 8° south of the Moon July 11,

and 90° west of the sun July 22, at which time he becomes an evening star. Mars is also advancing among the stars, moving from the middle of the constellation Pisces to 5° in Aries in July, keeping a little south of the Earth's path. There are no bright stars in his vicinity. Mars rises as follows:

July 10—11h. 48m. evening.
" 20—11h. 25m. "
" 30—11h. 0m. "

JUPITER will be in a very favorable position for observation and very brilliant throughout the month, rising as follows:

July 10—10h. 12m. evening.
" 20—9h. 30m. "
" 30—8h. 48m. "

He will be nearly 6° south of the moon July 8, and stationary July 2. He is retrograding or moving westward past the stars of the constellation Aquarius, being, in the latter part of the month about 8° south of the λ which marks the northern limit of the constellation.

JUPITER'S SATELLITES FOR JULY.

With an inverting telescope the Satellites will transit Jupiter from *right* to *left*, while the eclipses must *begin* at the *left* of the shadow and *end* at the *right* of it; also occultations begin at the left and end at the right limb of Jupiter's disc. The eclipses must all occur to the left of Jupiter for some time to come. For direct vision reverse the above directions.

SATELLITE I.	D.	H.	M.
Transit begins	4	3	38 morning
Occultation ends	5	3	6 "
Transit (shad.,) ends	3	11	13 evening
Transit ends	6	0	23 morning
Transit begins	11	4	19 "
Eclipse begins	12	2	32 "
Transit (shad.,) begins	12	10	47 evening
Transit, begins	12	11	53 "
Transit (shad.,) ends	13	1	7 morning
Transit ends	13	2	11 "
Occultation ends	13	11	22 evening
Eclipse begins	19	3	26 morning
Transit (shad.,) begins	20	0	41 "
Transit begins	20	1	40 "
Transit (shad.,) ends	20	3	1 "
Transit ends	20	3	58 "
Transit ends	21	10	25 evening
Transit (shad.,) begins	27	2	35 morning
Transit begins	27	3	26 "
Occultation ends	28	2	55 "
Transit begins	28	9	52 evening
Transit (shad.,) ends	28	11	23 "
Transit ends	29	0	10 morning
SATELLITE II.			
Eclipse begins	2	3	0 morning
Transit begins	3	11	43 evening
Transit (shad.,) ends	4	0	12 morning
Transit ends	4	2	34 morning
Transit (shad.,) begins	10	11	55 evening
Transit begins	11	2	9 morning
Transit (shad.) ends	11	2	49 "
Occultation ends	20	2	11 "
Eclipse begins	27	0	1 "
Transit ends	28	10	56 evening
SATELLITE III.			
Occultation ends	2	1	11 morning
Eclipse ends	9	0	12 "
Occultation begins	9	1	21 "
Eclipse begins	16	0	44 "
Eclipse ends	16	4	12 "
Transit ends	19	10	20 evening
Transit begins	26	10	20 "
Transit (shad.)	26	10	27 "
Transit ends	27	1	48 morning
SATELLITE IV.			
Transit (shad.,) ends	9	0	9 "
Eclipse begins	17	3	7 "
Transit ends	26	2	4 "

At the time of the beginning of the eclipse of Satellite IV (July 17, 3h. 7m. morning), the Satellites will occupy the following positions with respect to Jupiter: Satellites I and IV will be nearly equally distant at the right, and II and III on the left; II being half as far again east as I is west, while III is double the distance; direct vision being understood.

For the time of any of the above phenomena at any other place than New York City, *add* the difference of *time* if *east*, and *subtract* the same if *west* of New York.

SATURN will be 90° west of the sun July 7, being an evening star after that date. He will be 8° south of the moon July 11, and stationary July 28. He is moving eastward among the stars, and will be only about 1° southwest of Mars July 1. He rises as follows:

July 10—11h. 32m. evening.
" 20—10h. 53m. "
" 30—10h. 14m. "

EPHEMERIDES OF THE PRINCIPAL STARS AND CLUSTERS FOR JULY 20, 1879.

	H.	M.
Alpha Andromedae (Alpheratz) rises	8	17 even
Beta Persei (Algol) rises	9	57 "
Eta Tauri (Alcyone or the "Light of the Pleiades") rises	0	21 morn
Alpha Tauri (Aldebaran) rises	1	40 "
Alpha Auriga (Capella) rises	11	4 even
Beta Orionis (Rigel) rises	3	47 morn
Alpha Orionis (Betelguese) rises	3	32 "
Alpha Canis Majoris (Sirius)	invisible.	
Alpha Canis Minoris (Procyon)	invisible.	
Alpha Leonis (Regulus) sets	8	52 even
Alpha Virginis (Spica) sets	10	48 "
Alpha Bootis (Arcturus) sets	1	32 morn
Alpha Scorpionis (Antares) sets	0	52 "

	H. M.
Alpha Lyrae (Vega) in merid	10 39 even
Alpha Aquillæ (Altair) in merid	11 51 "
Alpha Cygni (Deneb) in merid	0 47 morn
Alpha Pisces Australis (Formalhaut) rises	10 57 even

EPHEMERIDES OF THE VARIABLE STARS, FOR JULY, 1879.

[NOTE.—That event which is *visible* is always given.]

Beta PERSEI (Algol).—*Minima:*

July 7—5h. 7m. morning.
" 10—1h. 55m. "
" 12—10. 44m. evening.
" 30—3h. 35m. morning.

Delta LIBRÆ.—*Minima:*

July 2—11h. 8m. evening.
" 9—11h. 43m. "
" 16—11h. 18m. "
" 23—10h. 53m. "
" 30—10h. 28m. "

All of these occur just prior to the *setting* of the star.

U CORONÆ.—*Minima:*

July 24—2h. 8m. morning.
" 30—11h. 52m. evening.

This star sets on the 24th, about 3h. 6m. morning.

spicuous, though large constellation. Above him, with head southward, stands Hercules, a large and rich constellation, having its northern part distinguished by a large trapezium of stars. The Nebulæ 13 Messier, which we alluded to last month, is near the northwest corner of this trapezium.

West of the Meridian.—The Zodiacal constellation, Libra and its Trapezium, and 35° north of it that beautiful cluster, the Northern Crown, easily distinguished by the crescent formed by six stars resembling a part of an inverted crown. Further west and in the Zodiac is Virgo, the "Nebulous Constellation," in which Sir William Herschel discovered 323 nebulæ. The brilliant star Spica is on the right hand, and (if the observation be made about an hour earlier, while Regulus is on the western horizon) will be found about midway between Regulus and Antares. Arcturus, in Bootes, is northward from Spica, and a line joining them makes two right angles, with Regulus on the west and Antares on the east. Berenice's Hair is a beautiful cluster nearly north of Spica.

East of the Meridian.—About 20° above the southern horizon is the northern part of Sagittarius, the Archer, containing the inverted "Milk Dipper," with its handle pointing west-

SITUATION OF THE PRINCIPAL CONSTELLATIONS, CLUSTERS AND STARS JULY 15, 1879, 9H. 0M. EVENING.

[NOTE.—The observer is supposed to be looking southward, and in Lat. 40° north.]

Near the Meridian.—Low in the south is the Milky Way, branching about 10° above the horizon and bending eastward. The Scorpion is the first constellation, curling his long articulated tail about in the Milky Way, almost touching the horizon. Antares, a brilliant fiery red star, may be seen 25° up. Next northward is Ophiacus, the Serpent Bearer, a very incon-

ward in the Milky Way. North of Sagittarius about 30° is Aquila, a small but interesting constellation, easily recognized by a line of three stars 3° apart, of which the central one is Altair, a splendid star of the $1\frac{1}{2}$° magnitude. The line of these stars continued 35° northwest reaches Vega, a star ranked, by most astronomers, as next to Sirius in brilliancy. This star will, owing to the precession of the eqinoxes, become the polar star, some 10,000 years hence, and will be within 5° of the equinoctal pole. It will be a fine sight to see, the stars which will then be northern circumpolar circling about such a

brilliant centre. A short distance west of the Harp is Cygnus, the Swan, containing a conspicuous figure resembling a cross with the bright star Deneb at its head. The tree of the cross lies in one of the richest portions of the *Via Lactea.* About 13° northeast of Aquila lies Delphinus, the Dolphin, easily distinguished by means of the four principal stars in the head, which are so disposed as to form a diamond, pointing N. E. and S. W. This cluster is commonly known as "Job's Coffin." Aries, in the Zodiac, is just rising.

METEORS.—July 3d-4th, 14th-17th, 25th-30th, are quite well-established shooting-star epochs. The last has its radiant near *Gamma* Cygni.

Penn Yan, N. Y.

Advice to Bathers.

With a view of diminishing the loss of life which annually occurs from drowning, the Royal Humane Society of England issues the following seasonable advice to bathers: "Avoid bathing within two hours after a meal, or when exhausted by fatigue or from any other cause, or when the body is cooling after perspiration, and avoid bathing altogether in the open air if, after being a short time in the water, there is a sense of chilliness, with numbness of the hands and feet, but bathe when the body is warm, provided no time is lost in getting into the water. Avoid chilling the body by sitting or standing undressed on the banks or in boats, after having been in the water, or remaining too long in the water, but leave the water immediately there is the slightest feeling of chilliness. The vigorous and strong may bathe early in the morning on an empty stomach, but the young and those who are weak had better bathe two or three hours after a meal; the best time for such is from two to three hours after breakfast. Those who are subject to attacks of giddiness or faintness, and who suffer from palpitation and other sense of discomfort at the heart, should not bathe without first consulting their medical adviser."

Accidents.

In the *Scientific American* of recent date, Prof. Wilder, of Cornell University, gives a series of rules for action in case of accident. Some of these rules are decidedly injudicious. Thus it is recommended to "remove cinders, etc., from the eye with the round point of a lead pencil." Unless in very careful and steady hands, hard substances should never be applied to the eye. A fine camel hair brush which has been moistened, the moisture squeezed out, and the brush drawn to a fine point, is the best thing. It absorbs the moisture at the point where the cinder lies, and the latter adheres to the brush and is easily removed. Where a fine brush cannot be had, a narrow strip of bibulous paper, such as printing paper, rolled spirally so that it may have a fine point, is the best thing. It will remove specks more certainly than any hard substance, and there is no danger of hurting the eye by an unsteady movement.

He also directs us to use "acids" as antidotes to acid poisons, but this must be a misprint.

Where it is necessary to pass through rooms filled with smoke, he directs us to "take a full breath and then stoop low, but if carbon (carbonic acid?) is suspected, walk erect.

It is well known that the air of a smoky room, if filtered through a wet cloth, is greatly purified. Therefore, the best plan is to throw a wet handkerchief over the face. Carbonic acid is always present where there is fire, but when heated it rises, so that the direction to walk erect is decidedly injudicious. In almost all cases the air near the floor is pure, because, a current of cool air from without sets in towards the fire, and of necessity passes along the floor.

Skeleton Leaves.

The following is a simple method of preparing skeleton leaves, and is decidedly preferable to the old and tedious method of maceration, as it is quite as efficient and not at all offensive. First dissolve four ounces of common washing soda in a quart of boiling water, then add two ounces of slaked quicklime, and boil for about fifteen minutes. Allow the solution to cool; afterwards pour off all the clear liquor into a clean saucepan. When this liquor is at its boiling heat place the leaves carefully in the pan, and boil the whole together for an hour, adding from time to time enough water to make up for the loss by evaporation. The epidermis and parenchyma of some leaves will more readily separate than others. A good test is to try the leaves after they have been gently boiling for an hour, and if the cellular matter does not easily rub off betwixt the finger and thumb beneath cold water, boil them again for a short time. When the fleshy matter is found to be sufficiently softened, rub them separately but very gently beneath cold water until the perfect skeleton is exposed.

The skeletons, at first, are of a dirty white color; to make them of a pure white, and therefore more beautiful, all that is necessary is to bleach them in a weak solution of chloride of lime—a large teaspoonful of chloride of lime to a quart of water; if a few drops of vinegar are added to the solution it is all the better, for then the free chlorine is liberated. Do not allow them to remain too long in the bleaching liquor, or

they will become too brittle, and cannot afterwards be handled without injury. About fifteen minutes will be sufficient to make them white and clean looking. Dry the specimens in white blotting paper, beneath a gentle pressure. Simple leaves are the best for young beginners to experiment on; the vine, poplar, beach and ivy leaves make excellent skeletons. Care must be exercised in the selection of leaves, as well as the period of the year and the state of the atmosphere when the specimens are collected; otherwise, failure will be the result. The best months to gather the specimens are July and August. Never collect specimens in damp weather, and none but perfectly matured leaves ought to be selected.

Inks for Rubber Stamps and Stencils.

Black.—Rub together one part of finest lampblack and 2 parts of Prussian blue with a little glycerin, then add 1 part of powdered gum arabic, and enough glycerin to form a thin paste.

Carmine.—Dissolve 24 grains of carmine in 3 fl. oz. of water of ammonia, then add 2 fl. drachms of glycerin. Incorporate with this ½ oz. of powdered gum arabic.

Blue.—Rub together 6 parts of pure Prussian blue and 1 part oxalic acid with a little water, to a perfectly smooth paste. Let it stand in a rather warm place over night, then rub it with more water, and with 1 part of gum arabic to a thin paste.

Aniline Inks may be made of any desired shade in the same manner. The best way of using these inks is by applying them, by means of a small pad, uniformly to a little cushion, on which the stamps are then inked.

The above formulæ have been furnished to us by a correspondent, who says he has tested them by experience, Another set of formulæ, also highly recommended, is the following:

Black.—Finest lampblack, 10 parts; powdered gum arabic, 4 parts; glycerin, 4 parts, water, 3 parts. Dissolve the gum arabic in the water, add the glycerin, then rub the lampblack with the mixture in a mortar.

Colored.—Replace the lampblack in the above formula by the appropriate color: chrome-yellow for *yellow;* red lead or red ochre for *red;* green, ultramarine, or chrome-green for *green;* indigo or Prussian blue, or blue ultramarine for *blue;* umber for *brown*, etc.

Removing Metal Splinters from the Eye.

The ragged chips and splinters which are separated during the processes of turning and chipping off, often find their way into the eye, and are sometimes very difficult to remove. The use of magnets has been recommended, but even the strongest magnet is entirely inefficient, if the splinters be imbedded. We have found a fine, sharp knife the best instrument, but it requires skill and a steady hand. The best method is that which a London surgeon thus describes in the *Lancet*: "In consequence of the difficulty I experienced in removing from a patient a portion of steel deeply bedded in the cornea, which did not yield to spud or needle, some other means of removal became necessary. Dry, soft, white silk waste suggested itself to me, and was wound around a thin piece of wood, so as to completely envelop its end. This soft application was brushed once backwards and forwards horizontally over the part of the cornea where the foreign substance seemed fixed. To my astonishment it was at once entangled by the delicate but strong meshes of the silk, and was withdrawn with the greatest ease, caught by the same. A gentleman in turning steel at a lathe suddenly felt that a portion had entered his eye. He went at once to a surgeon, who with the most skilful manipulation failed to extract the same, saying it would soon work out of itself. The next morning the patient saw me, having suffered severely since the accident, and on the first application of the silk, the portion of steel was extracted."

The Family Hammer.

There is one thing no family pretends to do without. That is a hammer. And yet there is nothing that goes to make up the equipment of a domestic establishment that causes one-half as much agony and profanity as a hammer. It is always an old hammer, with a handle that is inclined to sliver, and always bound to slip. The face is as round as a full moon and as smooth as glass. When it strikes a nail full and square, which it has been known to do, the act will be found to result from a combination of pure accidents.

The family hammer is one of those rare articles we never profit by. When it glides off a nail head, and mashes down a couple of fingers, we unhesitatingly deposit it in the yard, and observe that we will never use it again. But the blood has hardly dried on the rag before we are out doors in search of that hammer, and ready to make another trial. The result rarely varies, but we never profit by it. The awful weapon goes on knocking off our nails, and mashing whole joints, and slipping off the handle to the confusion of mantel ornaments, and breaking the commandments, and cutting up an assortment of astounding and unfortunate

antics without let or hindrance. And yet we put up with it, and put the handle on again, and lay it where it won't get lost, and do up our mutilated and smarting fingers, and yet if the outrageous thing should happen to get lost, we kick up a regular hullabooloo until it is found again. Talk about the tyrannizing influence of a bad habit! It is not to be compared to the family hammer.

Practical Hints.

Bleaching Piano Keys.—A writer in the *English Mechanic* says that the reason why piano keys turn yellow is because they absorb the grease from the fingers; it is therefore necessary to neutralize this. If a paste made from whiting and a solution of potash is laid on and allowed to remain for twenty-four hours, the ivories will be restored very nearly, if not quite, to their original color without removing them from the keys.

Bronzing Liquid.—Dissolve 10 parts of fuchsine and 5 parts of aniline-purple in 100 parts of 95 per cent alcohol on a water bath; after solution has taken place, add 5 parts of benzoic acid, and keep the whole boiling for 5 or 10 minutes, until the green color of the mixture has given place to a fine light bronze-brown. This liquid may be applied to all metals, as well as many other substances, yields a very brilliant coating, and dries quickly. It is applied with a brush,

Imitation Inlaying.—Suppose I want an oak panel with a design inlaid with walnut. I grain the panel wholly in oil. This is not a bad ground for walnut. When the oak is dry, I grain the whole of the panel in distemper. I have a paper with the design drawn thereon, the back of which I rub with whiting, place it on the panel, and with a pointed stick trace the design. I then with a brush and quick varnish trace the whole of the design. When the varnish is dry, with a sponge and water I remove the distemper, where the varnish has not touched. This, if well executed, presents a most beautiful imitation of inlaid wood. Marbles are executed in a similar manner.

Deceptive Vision.—There is a tendency in the eye to enlarge the upper portion of any object on which it looks—a fact which we find admirably illustrated by a row of ordinary capital letters and figures:

SSSSSSSSSSSXXXXXX3333333388888888888888

They are such as are made up of two parts of equal shapes. Look carefully at these, and you will perceive that the upper halves of the characters are a little smaller than the lower halves—so little that an ordinary eye will perhaps declare them to be of equal size. Now turn the page upside down, and, without any careful looking, you will see that this difference in size is very much exaggerated; that the real top part of the letter is very much smaller than the bottom.

Oleographs.—The beautiful cohesion figures formed by oil when dropped on water, are easily rendered permanent, and form very pretty ornaments, or if made in large numbers and kept in a portfolio, they are exceedingly interesting from their beauty and variety. Any one may produce them, figures and impressions, too, by the following simple means. Take a soup plate of water, let it stand till all the ripples have subsided, and then let fall in the centre one small drop of any oil that is at hand—salad oil, sperm oil, lard oil, or any other. The height of the fall should be about four inches. In an instant the drop spreads into a filmy disk, some four or five inches in diameter, and during the following two or three minutes a strange commotion is set up, the film breaking into circular holes sometimes of uniform size, at others in varying dimensions, according to the nature of the oil, and these are continually changing their configuration. At some points the whole will appear as a graceful pattern—it may be like a piece of ladies' crochet, or tatting work, or a simple reticulation, or a net work of beaded threads. To fix the pattern—to make the oleograph—it is only necessary to lay a sheet of glazed paper carefully upon the water's surface for an instant, and then float it upon a plate of common ink, or colored fluid of any kind. The paper will take ink where there is no oil, and leave the greasy markings intact. There you have your picture.

How to Keep Canary Birds.—Many persons have difficulty in keeping their canary birds in good health. One who is experienced in their care says: Place the cage so that no strong draft of air can strike the bird, and avoid also all exposure to the direct rays of the sun. Remember also that thin white cloth gives but little protection in summer from the sun's light and heat. Give nothing to the healthy birds but canary and rape seed, mixed with water, cuttlefish bone, and gravel on the floor of the cage; also, occasionally, a little water for bathing; the room should not be overheated; when moulting (shedding feathers) avoid drafts of air, give plenty of rape seed slightly moistened; a little hard-boiled egg and cracker grated fine is excellent, By observing these simple directions, birds may be kept in fine condition for years. Bad seeds kill most birds that die; to which it might be added, that canary birds are not only fond of but benefited by having often a leaf of cabbage, piece of apple, or other green food, which serves to keep down the tendency to fever and prevents constipation. Our birds usually bathe each day as regularly as any one who washes the face, and with apparent benefit, too. When birds are sick, and inclined not to eat well, remove all the food for a day, and then only give soaked bread, from which most of the moisture had been squeezed.

EXCHANGES.

A Smith & Wesson automatic ejector revolver, key check and stencil plate outfits, wanted for a combination saw, lathe, &c. Thos. D. Adams, Lock Box 61, Franklin, Pa.

J. T. Bell, Franklin, Pa., has brass condensing and exhausting air syringe, 100 good specimens (75 lbs) mostly silver ore, to exchange for gun, telescope, magic lantern, music box, or offers.

Wanted, back No.'s of the YOUNG SCIENTIST (for 1878), for a good dark lantern, cost $1.25. G. U. Bigelow, Palmyra, N. Y.

Duplicate collections of sea mosses from Oregon coast, for eye-glasses, back No.'s YOUNG SCIENTIST, or paper (working) pattern of best puzzle. Theo. Boone, Oneatta, Benton Co., Oregon.

Wanted, a microscope with accessories, in good condition, worth $5 or $10; state what is wanted in exchange. Will. H. Brewster, Middlebury, Vt.

Three vols. of Frank Leslie's Boys and Girls Weekly, cost $2.50 vol., to exchange 6 months for vol. 1 of YOUNG SCIENTIST, the rest for good books on electricity and science. Walter M. Brown, Owen Sound, Ont.. Canada.

Wanted, book, "Corner Cupboard or Facts for Everybody," in exchange for a card printer and type. H. E. Burnham, 176 Adams Ave. E., Detroit, Mich.

State what will be given for 250 foreign stamps, all different; list of other stamps sent on application. C. E. Chegwidden, 140th street, Mott Haven, N. Y.

Wanted, in exchange for good guitar, cost $25, a stationary engine, or bracket saw and turning lathe combined, or offers. Frankie Park, Dodge's Corners, Waukesha Co., Wis.

I have a magic lantern with 35 slides, cost $5; would like to exchange it for almost anything of similar value. Address all offers to C. Von Eiff, Box 4,465, City.

Fine carbine rifle, loads from muzzle or breech, in good condition; will exchange it for a double barrel shot gun, watch, or small rifle with bore 22-100. The Editor's Eye, 209 Rhodes Ave., Chicago, Ill.

Wanted, to exchange, North Carolina minerals, shells, stamps and Confederate money, for minerals, archæological specimens, Indian relics, vertebrate and invertebrate fossils, and curiosities for my museum. Robert H. Engle, Box 325, Raleigh, N. C.

Three volumes of Oliver Optic's (Wm. T. Adam's) works, Seek and Find, Fighting Joe, and The Yankee Middy, exchanged for cabinet mineral specimens. Anthony Garner, P. O. 53, Ashland, Pa.

To exchange, a seven shooting revolver of best make, in good condition, size of bore 22-100 in.; state what is offered in exchange. H. V. H., P. O. Box 47, Coeymans, Albany Co., N. Y.

Fairbank's No. 1 chemical scales and weights, cost $15, for a bracket saw with or without lathe attachment; scales warranted perfect; will give a *good* trade. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, double-barrel shot-gun or scroll saw, in exchange for telegraphic key and sounder on one base, Craig microscope, etc. C. H. Jordan, Shimersville, Lehigh Co., Pa.

Unmounted microscopic objects such as foraminifera, spicules, starches and parts of foreign insects, &c., to exchange for other mounted or unmounted objects. S. N. Hardy, Victoria, Cass Co., Neb.

A complete outfit for making chromo photographs and a small magic lantern and slides, worth $10, for a 5x7 printing press, or type, or a combination scroll saw and lathe. Geo. L. Lamson, La Fargeville, N. Y.

An oscillating steam engine, 1-inch bore, 2-inch stroke, to exchange for a household microscope, or offers. L. E. Kent, Santa Ana, Los Angelos Co., Cal.

Lippincott's, $4.00; Popular Science, $5.00; Phrenological, $2.00; Sanitarian, $3.00; Library, 3 copies $1.00 each; Housekeeper, $1.00; all monthlies, 1879, complete; Daily Sun, N. Y.; Star, Cincinnati, 1 year, $5.00; make offers. C. H. Kimball, Plymouth, N. H.

Wanted, correspondents to exchange insects with; will send full instructions for capture and make liberal exchanges. C. W. L., Box 3,565, N. Y. City.

Choice cabinet mineral specimens, for historical, scientific, masonic or other instructive books. C. A. Leeper, Bonanza City, Lemhi Co., Idaho.

To exchange, certificate for a course of lessons in shorthand writing, for books, or offers; also copies of the Student's Journal, for copies of YOUNG SCIENTIST; state what numbers you can furnish. H. C. Lucas, Macomb, Ill.

Wanted, all numbers of the YOUNG SCIENTIST for 1878, in exchange for the Story of a Bad Boy, or Chance for Himself; each cost $1.25. Jesse H. McIntire, Rockport, Mass.

Wanted, Queen's or McAllister's Household microscope; specimens of insects, woods, &c., in exchange; or state what is wanted. W. C. McNaul, Salina, Clinton Co., Pa.

Minerals, fossils, Indian relics and foreign stamps wanted, in exchange for same, or for greenhouse plants. Send list to Wm. J. Morgan, Somerville, N. J.

Wanted, a good wood lathe with attachments; state what is wanted in exchange, giving description of lathe. C. W. Munson, Nashville, Tenn.

Wanted, printing press, for a scroll saw and tools for finishing work. T. H. Nicholson, 14 East 127th St., N. Y. City.

To exchange, a novelty printing press, type and accessories, for a microscope with accessories, or minerals, or offers. T. W. Patterson, Warsaw, N. Y.

Wanted, a small printing press, Model or Novelty preferred, in exchange for a French microscope, objects and accessories, worth $20. C. L. Peticolas, 635 8th St. North, Richmond, Va.

Wanted, stereo camera with lens, ½ size view camera and lens, photo chemicals or offers, for rosewood writing desk inlaid with mother of pearl, and complete rosewood box of drawing instruments. A. B. Porter, 501 North Tenn. St., Indianapolis.

Wanted, a turning lathe from ½ to 2 inches swing; state what is wanted in return. Grant Price, Lock Box E, Cherokee, Crawford Co., Kan.

Wanted, a good set of engravers tools and a book of instruction, in exchange for an aquarium. H. E. Rhodes, Brighton, Iowa.

Wanted, to exchange, books for type; send specimen of printing of type; also state weight of font &c. J. Siler, 1,242 Broadway, St. Louis, Mo.

To exchange, a new book on fret sawing and wood carving, well illustrated and very handsomely bound, for good mineral specimens; also coins to exchange for minerals, &c. A. H. Spencer, East Clarendon, Vt.

Wanted, a good microscope or a pair of telephones, or other apparatus, in exchange for a photographic camera, lens, plate-holder, tripod, &c., valued at $5, entirely new, and enclosed in a neat case. Sheldon Sperry, 99 Lee Ave., Brooklyn, E. D., N. Y.

A collection of foreign and U. S. stamps, some paints and colored pencils, in exchange for Indian relics. Sherman Sweeting, South Butler, Wayne Co., N. Y.

A strong magnet, in exchange for Indian relics. Sherman Sweeting, South Butler, Wayne Co., N. Y.

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. II. NEW YORK, SEPTEMBER, 1879. No. 9.

Hardening and Tempering Steel Tools.

THE following thoroughly practical article on hardening and tempering steel tools, was contributed by Mr. Jas. Nasmyth to Northcott's work on "Lathes." As it is especially suited for amateurs, we reproduce it:

Whatever be the efficiency of the construction of a lathe, or other machine for cutting metal and other materials, the excellence of the result must ultimately depend not only on the proper form of the tool which operates on the work, but also on its capability to retain its cutting edge. This depends on the tool possessing the proper degree of hardness and temper.

Before proceeding to the immediate subject of these remarks, it may be as well to say a few words on the subject of the treatment of steel in forging it into the form of the tool required. In this respect, whatever be the form of the tool, it is most important for the preservation of the original good quality of the steel that, in forging it into the required form, the lowest degree of red heat should be given to the steel as may be consistent with its capability to receive the desired form by the action of the hammer. Any degree of heat beyond that which is just visibly red in daylight, risks a permanent injury to the quality of the steel.

In forging all such tools as are of a flat form, it is highly desirable that the finishing blows should be given on the flat, and not on the edge or sideways of the tool. Attention to this apparently trifling observation will be well rewarded by the enhanced durability of the tool so produced.

In respect to "hardening" and "tempering" of steel tools, they are two distinct processes; hardening first, tempering afterwards. The first induces the maximum of hardness, accompanied by brittleness; the second has reference to modifying that hardness, and so gaining in exchange a certain degree of toughness.

For the majority of tools employed in

self-acting lathes and planing machines, in which cast iron, steel, and brass, is turned, or planed, steel tools when properly *hardened* are best fitted to withstand the duty required of them, no *tempering* or modification of their original hardness being requisite or desirable.

In order to "harden" such tools, all that is requisite is to heat the operative part to *just* such a degree of red heat as that when plunged into cold water they shall just become hard—any degree of heat beyond this will prove seriously injurious to the capability of the cutting edge in preserving its keenness and power of resisting the strain of the cut. Such a degree of red heat as will be barely visible in daylight, is ample to cause steel to acquire the maximum of hardness when plunged into cold water.

Want of due care and attention to these conditions in hardening steel is a more fertile source of failure and disappointment than many are aware of. If those who have to do with practical management of machines requiring the use of steel tools would carefully attend to the above observations, the results would well repay them for the special attentions given to the subject.

In the case of such tools as are employed in the generality of wood-turning, and for screw-taps, drills, chipping chisels, and the like, the process of "tempering" is requisite.

Tempering in this case, as the word signifies, is the modification to a greater or less degree of the original hardness and brittleness, due to and natural to the process of hardening. Tempering, in fact, is the process whereby we exchange some of the original hardness in order to gain a corresponding equivalent of toughness, and is attainted by re-heating to certain degrees the original hardened tool.

The mode by which this tempering process is most conveniently attained is by grinding the part of the tool we desire to temper so as to render it bright, and then, by resting it on a piece of red-hot iron, we thereby communicate to our hardened tool such a degree of heat as shall modify or "let down" the hardness, and induce such a degree of toughness as will best suit the requirements of the case. The progress of re-heating effected in this manner is easily observed by the brightened surface of the tool acquiring in succession a series of prismatic colors. Thus:

1st. Pale straw color.
2d. Brass color.
3d. Deep brass color.
4th. Reddish purple.
5th. Purple.
6th. Blue.
7th. Slate blue.

Beyond slate blue all remaining hardness, such as is required for the generality of purposes, terminates, and the steel returns to softness.

According to the purpose to which the tool is to be applied, the degree of temper or modification of the original full, hard condition may be arrested by plunging it into cold water the instant the color indicating the desired "temper" has come on. 1, 2, 3, as from the above list, serve well for most wood-turning tools. 3 and 4 for screw taps and drills, and for chisels for chipping iron and brass. 5. 6, 7, for springs or such purposes where a certain degree of elasticity may be required in conjunction with a very moderate degree of hardness.

To say nothing as to the importance to practical mechanics of a thorough knowledge of the art of hardening and tempering steel, on which the final efficiency of all our lathes, planing and other metal working machines depends, we would earnestly recommend to the amateur workman to devote a few hours to acquire the art of hardening or tempering steel in accordance with the brief practical hints we have endeavored to give in the preceding remarks on the subject.

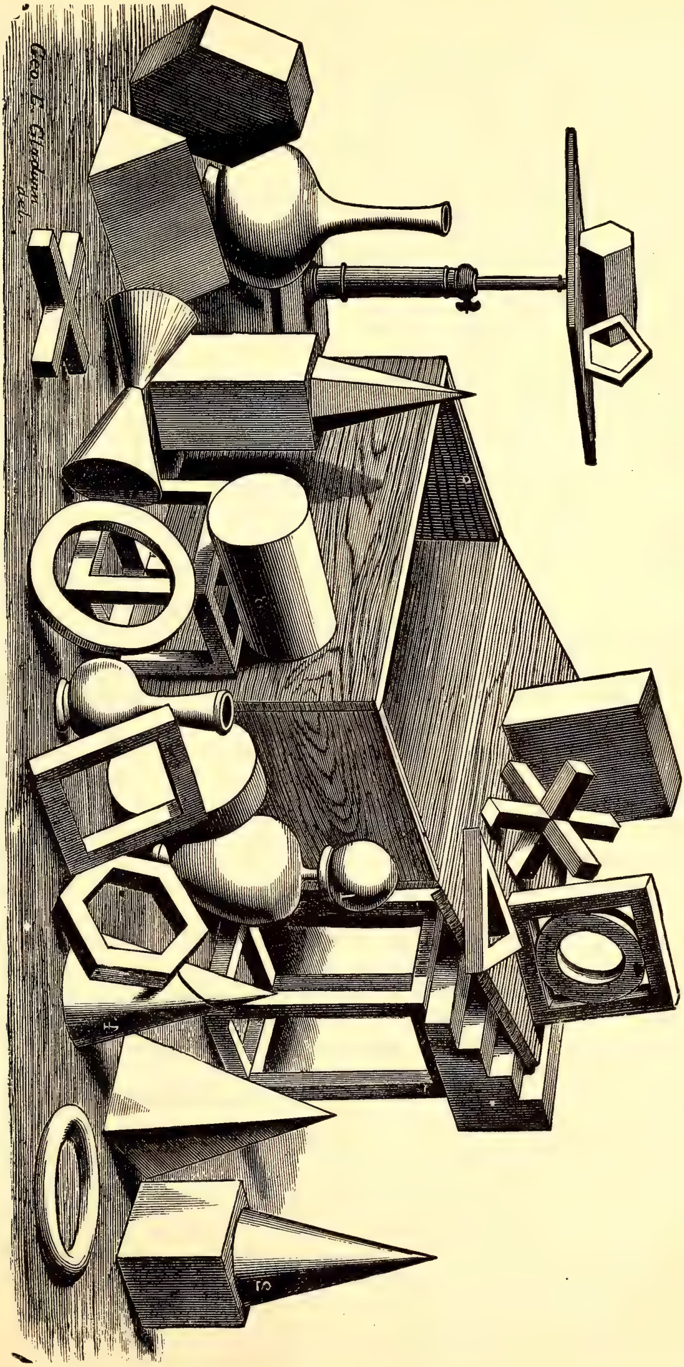
Drawing Lessons—III.

BY JOHN CLARK CENTER.

Drawing Models.

As it may be difficult for some of our readers to procure "The Geometrical Models," as subjects for study, we furnish by our full-page illustration a grouped collection of the most important ones used in art educational schools.

The five primary solids are the cube, the



THE GEOMETRICAL MODELS.

pyramid, the cone, the cylinder, and the sphere. To these all natural and artificial objects bear some resemblance. For instance we find the sphere in the orange, apple, etc. The cone we find in the carrot, the trunk of trees, etc., and so on indefinitely with the others. The importance of the study of geometrical figures and mathematical solids will be apparent to all, in the study of freehand and mechanical drawing.

Let the student select for practice, say the cone, the cube, the pyramid, and circular ring, at the right hand of the engraving; draw them at least four times the size, and attempt to shade them. In shading with the lead pencil use a rather flat point. The parts in shade cover with a uniform tint, adding depth and strength gradually, following the same direction of line as in copy. This will enable you to see the outline assume the solid form. The art of shading, however, will be treated fully upon at a more advanced stage.

We would, however, caution some at this point not to try too much at first, as the great object is to master an exact outline; many fail by trying to hide this defect by a spurious and indiscriminate blending of shades, which the uneducated eye thinks pretty. This is death to all progress. Let the student continue to select other groups, and treat them in like manner, by which means alone he can become familiar with the proper forms. In drawing the box with the lid open, you will have a practical test of the former lesson. In every case the nearest parallelogram must be first drawn, then the whole figure to which it belongs. Auxiliary test lines will suggest themselves to find the angles of the next object, and so on.

The cylinder will require some special attention in its treatment as a study, as the circle has to undergo an indefinite number of changes in relation to its position with the eye. It is often difficult with both young and old to understand the plane of a circle or orbit. Perhaps as ready a method as any, is to take a ring or hoop, which at once describes a circle, or orbit, and turning it in various directions in the hand show the alteration of the plane. It then assumes an oval form, more or less broad, according as it is more nearly level with the eye, or more below it.

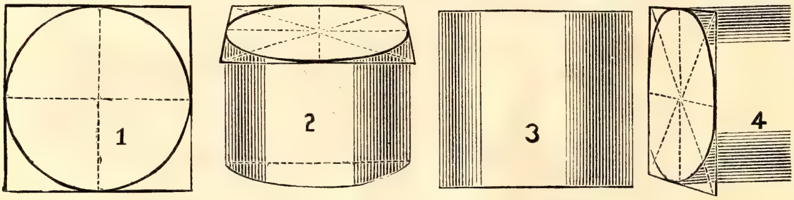
It appears as a straight line when exactly level with the eye. The following diagrams will convey this idea in a very simple manner.

If the ends of a cylinder be presented directly in front of the eye, we have the circle. If it stands on end, and is viewed obliquely, we have the oval; its method of construction is indicated in Fig. 2. Here we have the top of the cube in perspective; by drawing the diagonals we have at the point of intersection the centre, through which draw the bisecting lines. The oval can now be drawn in easy sections, observing that the half furthest from the eye is the smallest. This same law holds good on all sides of the cube, and the oval form that the circle assumes under all conditions, is to be determined by the parallelogram that a square describes seen in perspective.

Fig. 3 shows a straight line, as the eye is on an exact level with the object.

Fig. 4 shows the cylinder in a horizontal position viewed from the end.

All the other geometrical forms, the pentagon, hexagon, etc., etc., follow the same laws of construction when drawn in



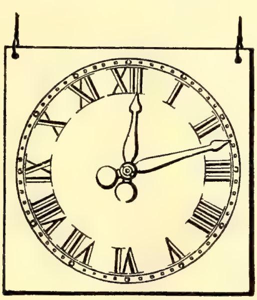
THE CIRCLE AS SEEN FROM DIFFERENT POINTS OF VIEW.

perspective, and will call for a good deal of ingenuity and skill to master them perfectly.

By a proper study of our model plate, (where the originals cannot be procured) the ability to draw objects from nature may be cultivated. The student will find more difficulty in this than in merely copying lines already laid down, unless he understands what we have taught in the former lessons, which are but as the alphabet to be used in connection with the laws of perspective, to determine nature, and present in your work a mirror of truth.

Mysterious Clocks.

THERE is at the present time quite a furor for mysterious or magic clocks which shall puzzle the observer to tell how they are driven. One of the simplest and best is that shown in the engraving. The clock apparently consists of a square plate of glass which is suspended by cords, so as to be entirely unconnected with any mechanical source of power. On this



MAGIC CLOCK.

plate are marked the figures for hours and minutes, and attached to the centre are two hands which move round the dial and point to the time with considerable accuracy. A very curious feature of this clock is the fact that the hands seem to turn loosely on the central point, and if twirled around any number of times, will settle back to the right place, even making allowance for the few seconds in which they have been moving. They may also be taken off and laid away for some hours, and when again placed in position, they will indicate the correct time.

The secret of this clock lies in the counterpoises attached to the hands. These counterpoises contain the works, and the positions of the hands are determined by weights which these works move out and in from the centre, thus giving the weights greater or less leverage, and causing the hands to act in the same way as the well-known bent lever balance.

The New Copying Process.

SOME time ago, a new method for rapidly producing copies of letters, or any kind of written matter, was made the basis of a patent in Austria. The simplicity and facility of working the apparatus immediately attracted universal attention, but the high price of the first apparatus was not at all in proportion to the cheap materials, even allowing for a very respectable profit. It was soon ascertained that the process, or rather the composition of the printing material, was not capable of being patented, being nothing else than gelatine (or glue) and glycerine. Since then, in Europe as well as in the United States, a number of such apparatus, have made their appearance under various names, such as Copygraph, Copygram, Hectograph, Lithogram, Cheirograph, Autograph, Multigraph, etc. Competition has so reduced the prices of these that they are now sold at not unreasonable rates, and many will prefer to buy them ready made with all the necessary appliances. But for those who wish to make an apparatus for themselves, we append several methods:

1. Take one part by weight of gelatine (glue does just as well), let it swell in two parts of water, melt, and add four parts of (common) glycerine, with a few drops of carbolic acid, and sufficient whiting or white lead to make the whole milky. Pour the mixture into a shallow tin or zinc dish; it will be ready for use in about twelve hours.

2. Ten parts of gelatine are softened in water, and then dissolved in 100 parts of concentrated glycerine, on the water-bath. When melted, the mass is slowly and carefully poured into a tin-tray, about $\frac{1}{2}$ cm. ($\frac{3}{8}$-$\frac{3}{4}$ inch) deep, and of any desired

size. Any rising air bubbles must be removed, and the mass is then allowed to become cold, when it will form an elastic mass, a little firmer than printer's rollers. Other formulæ substantially the same, but with slight changes in the proportions, and the addition of various unimportant ingredients, have been published. In any case the resulting mass has the property of absorbing to the depth of perhaps 1-64 inch writing or tracings made with certain kinds of ink, particularly aniline-inks. Any aqueous ink would answer, but it is necessary to use one which is made of a very persistent color. The writing desired to be multiplied is written upon a sheet of paper with the special ink described hereafter; after the ink is completely dry, the sheet is laid on the moistened gelatine-surface (writing down). and gently rubbed over with the hand. After a short time (about half a minute), the paper is removed and laid aside. Fresh paper being ready, a sheet is laid upon the writing, and the hand gently rubbed over the back, when a clear and complete copy of the writing will be found on the paper. This may be repeated from sixty to a hundred times, according to the quality of the ink, and the experience of the operator. When no more copies are wanted, or when the ink is exhausted, the surface is washed off with a sponge and cold water. Any traces of the ink left in the mass, after thoroughly washing, will not interfere with the next copy. When necessary, the mass in the tray may be remelted.

The ink may be prepared as follows:

Violet: methyl-violet, 2: dilute acetic acid, 2; water, 4 parts.

Or, *red:* fuchsine, 2; alcohol, 1; water, 8 parts.

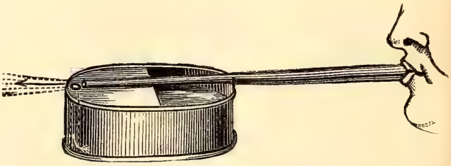
Or: Mix 5 parts of any desirable aniline color, 5 of alcohol, 5 of mucilage, and 35 of water in a flask, heat until dissolved, and after 24 hours strain through flannel or wool. The selection of aniline-colors is difficult, as many of them are largely composed of *dextrin*, which dries up or makes the solutions thick. The best aniline color, according to E. Störmer. is the Violet de Paris de Poirrier.

This apparatus is specially valuable to microscopists and naturalists, who require a few dozen copies of exchange lists or descriptions of apparatus. To have such lists printed is a process altogether too expensive, while few are able to afford electric pens and similar apparatus. The simple contrivance which we have described, and which may be made at an expense of a few dimes, answers every purpose.

A New Form of Sprinkler.

A SIMPLE method of distributing a liquid in fine spray, is one much needed in many operations. The old-fashioned sprinkler with its nozzle perforated with numerous holes, is probably the oldest device of the kind, but it is a very imperfect one. The method used by those who practice "spatter-work" gives finer spray, but lacks the ability to give sufficient quantity to moisten articles, such as paper, cloth, etc., thoroughly.

One of the most perfect contrivances of the kind that we have seen, consists of an application of the atomiser, and is in use amongst silk-manufacturers for moistening the silk during certain processes. It is very simple and easily made, as will be evident from the accompanying engraving. It consists of a tin vessel



ATOMIZER FOR SPRINKLING.

across the top of which is fixed a tube through which air may be blown. The tube is supported by the edge of the vessel and also by a tin plate which covers half the vessel next the mouth of the operator. The point of the tube ends about an inch from the opposite side of the vessel, and on a level with the edge. When the vessel is filled with water, and a blast of air is sent through the tube, the water is lifted up and scattered in the finest spray. As the liquid sinks in the vessel, the apparatus is tipped so as to bring the water up to the edge, and in this

way the last drop may be dispersed in spray.

The applications which might be made of this simple device are almost innumerable.

Puzzles as Mental Exercises.

THE following puzzles are good, considered merely as puzzles, but when analyzed, as we find them in the *Household*, so as to show the particular way in which the mind is led astray from the correct answers, they become most interesting and valuable studies:

"Two brothers," began the Professor, impressively addressing the hostess, "were walking together down the street, and one of them, stopping at a certain house, knocked at the door, observing, 'I have a niece here who is ill.' 'Thank heaven,' observed the other, 'I have got no niece,' and he walked away. Now how could that be?"

"Why, it's a riddle!" exclaimed Mr. Funnidog, delightedly.

"And one that you will not guess in a hurry, simple as it is," observed the Professor confidently. "Come, ladies and gentlemen, solve the problem."

"I see——," ejaculated Mrs. Housewife.

"Hush! whisper in my ear," cried Puzzleton, with all the excitement of a child with a top. "Don't let 'em hear it. 'Niece by marriage.' Stuff and nonsense, The thing is not any foolish kind of catch at all;" and once more he glanced with hostility at Funnidog, as much as to say, "Such as he would ask you." Nothing can be simpler than my question. "I've got a niece, that's ill," says one brother. "Thank heaven, I have not got a niece," says the other. "How can that be? You all give up? Well, the invalid was his daughter."

"Oh, I see," said Mrs. Housewife despondingly. "How very stupid in us not to find it out.

"Yes indeed, ma'am," answered the remorseless savant. "That failure only shows how difficult it is for ordinary minds to grasp more than one idea at the same time. The attention is solely fixed on the different varieties of nieces."

"And, also," observed Mr. Aloes (who was much displeased at being classed among "ordinary minds"), "and, also, the attention is naturally distracted from the point at issue by the brutality of the father's remark. Now that is in itself 'a catch,' in my opinion."

"Well, Sir, I will give you another simple exercise for the understanding that has no such distracting element," observed the Professor, cooly. "A blind beggar had a brother. The brother died. What relation were they to one another? Come, tell me that."

"Why, they were brothers," exclaimed the colonel, with the rapidity of a small boy at the bottom of his class, who hopes to gain promotion.

"No, sir," answered the Professor, regarding Thunderbomb with interest, as a significant type of some low order of intelligence, "they were not brothers, or I should scarcely have asked the question."

"They might be brothers-in-law," suggested Funnidog.

"Undoubtedly they might," replied Puzzleton, with a pitying smile; "but they were not."

"Stop a bit," said McPherson, hurriedly, like one who has not got his answer quite ready, but yet doesn't wish to be anticipated. "The blind beggar, you said, had a brother, and the brother died. Well, of course, if one was dead, you know they could not be brothers any longer."

"The idea is novel," observed the Professor, gravely, "but you have not hit upon the exact solution. The fact is, gentlemen and ladies, a blind beggar may be either male or female. In this instance she was a female. They were brother and sister."

"I call that a catch," said Aloes, gloomily.

"Well, at all events, it was an easy one, and you all missed it," returned the Professor, with quiet triumph. "Now, I will give you one more example of social arithmetic, which will be in all respects *bona fide*. It is a simple question in subtraction, and all I ask of you is—since two or three guesses would arrive at the truth by mere elimination—to write down the reply on paper. A man went into a

cobbler's and bought a pair of boots for sixteen shillings. He put down a sovereign (twenty shillings), and the cobbler having no change, sent to a neighboring public house, and gave it to him. Later in the day, the landlord of the inn sent in to say that the sovereign was a bad one, and insisted upon the cobbler making it right; which he accordingly did. Now, how much did the cobbler lose by the whole transaction? There is no play upon words, or anything but a common sum in arithmetic."

"Why, it's the easiest thing in the world," ejaculated Housewife. "Of course the cobbler lost just—"

"Be quiet, sir!" cried Puzzleton very angrily. "Write it down, will you, if you can write."

"Scratch a Professor, and you find a Tartar," whispered Aloes. "You had better do as he wishes."

So we all wrote down what we imagined to be the loss which the cobbler had sustained; and it was wonderful how opinions differed within such narrow limits.

The colonel made him lose two pounds.

Mr. Aloes made him lose just a pound and the boots.

Mr. Funnidog made him lose six and thirty shillings.

Mr. McPherson made him lose sixteen shillings and the boots, minus the profit he made upon the boots (which, the Professor said, was not necessary to take into consideration.)

Mr. Scale Hill, who used to investigate the bills of extortionate Swiss landlords, set down the loss with confidence at twelve shillings and the boots.

Housewife wrote:—"Why, of course, he lost the boots and twenty-four shillings."

Mrs. Housewife and the ladies bit their pens, but declined to commit themselves. "They had never been taught," they said, "the Rule of Three."

"You are all wrong," said the Professor, quietly, "as I expected you would be. The way to get at the matter is to consider what is gained. The landlord and his whole story of changing the sovereign may be taken out of the question, since he is neither better nor worse for the transaction. The buyer of the boots gets in exchange for his bad sovereign four shillings and a pair of boots, and that is just what the cobbler loses."

"If one only had a room to one's self, and the whole day before one to do it in," sighed Mrs. Housewife; "I think I could answer any of these questions."

Paper Flower-Making.

PAPER flower-making may in some sense be regarded as a fancy industry for ladies; inasmuch as small manuals of instruction in the art have been published for their use, and sets of necessary appliances prepared for sale. Nevertheless, this is but an offshoot from the larger trade occupation. The tools necessary are very simple. Pincers to hold the small piece of paper firmly, and to assist in preparing the petals; "ball-tools" of various diameters to work the petals into a hollow form; or crimping or gauffering tools, to give the marking to leaves, etc., are the principal. Of the materials, the chief, of course, are paper, used for the petals, leaves, and buds; it is sold in sheets of almost infinite varieties of color, or in pieces so far shaped, crimped, and gauffered, as to expedite the labors of the flower-maker. The few other materials for buds, stalks, etc., are likewise sold distinct by the flower-material dealers. The ball-tools above-named, vary from half an inch to an inch and a quarter in diameter; the smaller sizes being used in preparing the rose, poppy, carnation, etc., the largest for the cactus, dahlia, etc. Taking the poppy as a typical example of a flower to be imitated in paper—nine pieces of paper are cut out, with scissors or with some kind of stamp; some notched on the edge, some indented at definite distances apart. These pieces, intended for the nine petals, are gauffered one by one, by drawing up the edges around a finger placed in the middle. They are then threaded together at the centre with a fine wire, and cemented at the proper spots with gum; the heart, bud, leaves, stamens, pistil, calyx, etc., being fixed in their proper places. The wire is covered with green paper of the proper tint for forming the stem, by coiling a narrow

strip around it, the thicker stalks being swelled out by a layer of white carded cotton under the paper. The smaller stalks, to which the buds, leaves, and flowers are attached, are fastened to the larger stalks by silken threads and paper fillets. And thus is a flower poppy built up.

Select any one among a score of the beauties of the flower-garden, and the processes are in a great measure the same, the details only differing in each case. The number of pieces of paper required for the petals, leaves, buds, etc., their sizes and shapes, colors and shades, notchings and indentings, gauffering and crimping, the threading and gumming of the petals, the degree of rolling and unrolling necessary for the full-blown or half-blown condition of the flower, the imitation of the delicate tendrils of certain flowers by means of very fine twisted wire, the imitation in Indian ink of the black markings which occur in the insides of certain other flowers—all have to be attended to, if possible, with real flowers as guiding patterns. Where a flower comprises twenty, forty, or even sixty petals (which is sometimes the case), the building up or mounting calls for the exercise of much tact. For some flowers, such as the camelia, Chinese rice-paper is preferred, on account of its softness and translucency; but being brittle, it requires care and delicacy in handling.

The Six Follies of Science.

THE six follies of science are said to be the following: The quadrature of the circle; the establishment of perpetual motion; the philosopher's stone; the transmutation of metals; divination, or the discovery of secrets by magic; and lastly, judicial astrology. It is perhaps unwise to say that anything is impossible, until the impossibility is demonstrated, but it is certainly not the part of a wise man to attempt the solution of any question by mere hap-hazard guess work. With perhaps a single exception, all the problems above set forth have been proved to be impossible, because they distinctly and unequivocally contradict great natural laws.

Editorial Notes.

Home Arts.

NEARLY every reader of the YOUNG SCIENTIST must have heard of that pleasant little journal—HOME ARTS, the publication of which was commenced a few months before that of the YOUNG SCIENTIST. It was a bright little journal, ably edited and managed by a well-known publisher, whose success with *The Little Corporal* would have seemed to guarantee that of HOME ARTS. But to the everlasting discredit of those who prate about their disgust of low, story-telling papers, (and their number is enough to have supported ten such journals), HOME ARTS never had a subscription list large enough to pay expenses. It has, therefore, been consolidated with the YOUNG SCIENTIST. The following card from the publisher of HOME ARTS tells its own story:

To Subscribers to Home Arts:

As we found the publication of HOME ARTS unprofitable, and could not afford to continue it longer at a loss, we have arranged with the publishers of the YOUNG SCIENTIST to send two numbers of that journal for every single number of HOME ARTS due to our subscribers. Hoping that this will be will be more than satisfactory, and that all our patrons will become permanent patrons to the YOUNG SCIENTIST, we bid them good speed.

PUBLISHER OF HOME ARTS.

In carrying out this arrangement we have adopted the following plan: As the last number of HOME ARTS that was issued was that for November, 1878, it might have been proper to begin with the YOUNG SCIENTIST for December, 1878. As, however, the numbers of the YOUNG SCIENTIST form each year a complete and handsome volume, we have omitted the number for December, 1878, (which would have been an odd one) and have commenced with that for January, 1879. To all subscribers to HOME ARTS, therefore, we have sent as many numbers (commencing with January, 1879) as are due them. Those to whom more than nine numbers are due will receive the numbers due as fast as issued. Those who were subscribers to

both journals will have their subscriptions to the YOUNG SCIENTIST extended by the proper amount.

BOOK NOTICES.

The Workshop Companion: A Collection of Useful and Reliable Recipes, Rules, Processes, Methods, Wrinkles and Practical Hints for the Household and the Shop. Price, 35 cents. New York: The Industrial Publication Company.

There is, probably, not a single reader of this notice that has not at some time or other felt the want of some item of information contained in this book, and would gladly have given the price of the volume for one of the recipes. The book covers a very wide range of subjects, there being no less than ninety main articles, some of which contain as many as sixty sub-headings. The pages are of good size and closely printed in very clear type, so that 164 of them contain an unusual amount of matter. The subjects are arranged alphabetically, the work thus forming an almost complete encyclopædia of practical, everyday information.

The thoroughness with which the book has been prepared is best seen by examining a few special subjects. Turning to the article on *Cements*, we find not only a short treatise on the use of cements, but a series of nearly sixty recipes, covering every possible requirement, from aquaria to steam boilers.

Again, under the head of *Inks*, we find not only a series of recipes for almost every variety of ink, but a carefully written article on the selection and use of ink, giving information which is of service to every one, and which but few people possess. The same might be said of *Alloys, Lacquers, Steel, Brass, Wood Finishing, Polishing Powders*, etc., to the extent of nearly one hundred distinct subjects. In every case, so far as we can judge, the information given is reliable, and its general usefulness is shown by the fact that in almost all cases it covers the popular uses of the articles as well as their strictly technical relations. Thus, under the head of *Marble*, we find not only directions for working and polishing it, but for preserving and cleaning it, and also hints as regards the ways by which marble articles may be injured.

The publishers undoubtedly anticipate for this book a very large sale, or they could not have made the price so low in proportion to the amount of matter given.

Devices of Autumn Leaves.

An exquisite transparency may be made by arranging pressed ferns, grasses, and autumn leaves, on a pane of window-glass, laying another pane of the same size over it and binding the edge with ribbon, leaving the group imprisoned between. Use gum-tragacanth in putting on the binding. It is well to secure a narrow strip of paper under the ribbon. The binding should be gummed all around the edge of the first pane, and dried before the leaves, ferns, etc., are arranged; then it can be neatly folded over the second pane without difficulty. To form the loop for hanging the transparency, paste a binding of galloon along the edge, leaving a two-inch loop free in the centre, afterwards to be pulled through a little slit in the final binding. These transparencies may be either hung before a window, or, if preferred, secured against a pane in the sash. In halls, a beautiful effect is produced in placing them against the side-lights of the hall door. Where the side-lights are each of only a single pane, it is well worth while to place a single transparency against each, filling up the entire space, thus affording ample scope for a free arragement of ferns, grasses, and leaves, while the effect of the light passing through the rich autumnal colors is very fine. Leaves so arranged will preserve their beauty the entire winter.

An exceedingly pretty standing for a lamp can be formed of eight oblong transparencies (made of glass and autumn leaves as described) tacked together with strong sewing-silk so as to form an eight-sided hollow column. To hide the lamp candlestick, the screen should be lined throughout with oiled tissue paper, either white or of a delicate rose-color. A better plan still is to get the effect of ground glass by rubbing each strip of glass on a flat paving-stone, plentifully covered with white sand. This grinding process, of course, must be performed before the leaves are inserted, and then only upon the inner side of the glasses. The completed screen may have a simple border of heavy chenille at the base, or be placed upon an unvarnished black-walnut stand decorated with acorns, pines, cones, etc. The screen is of course left open at the top. It must be set over a lighted candle or small lamp to give its best effect, though it is also a very ornamental object in the daylight.

Curious Experiment.

Suppose you were required to take a coin from the bottom of a deep jar, or even a pail of water without wetting your hand, and suppose further that your naked hand was to be thrust through the water, how do you suppose it could be done? Simply by shaking a little lycopodium, (a substance that may be procured cheaply at any drug store), over the surface of the liquid. Then plunge your hand boldly but steadily into the water and it will not wet you in the least, The cause of the water's not wetting the hand is the same in principle as that which causes the dew to stand in spherical drops on the

cabbage-leaf, and the water to roll off the duck's back without wetting it. By a somewhat similar power, spiders and other insects walk on the surface of water without wetting themselves, and without sinking in the liquid to any perceptible degree.

We have sometimes seen the following solution of this problem offered: Fill a plate with water to the depth of about a quarter of an inch; a coin is then placed in the water; a piece of paper is lighted, and put, while burning, on the surface of the water, and covered with a tumbler. As the paper burns under the tumbler, the water will rush up under the tumbler, and leave the coin in the plate, when it may be lifted without wetting the fingers. This is a very interesting experiment, as it affords a good illustration of the expansive power of heat, and of the pressure of the atmosphere. But when we remove the water by atmospheric pressure, it is after all merely a scientific way of pouring the water out of the plate.

Practical Hints.

Price of Rare Metals.—Dr. Theodore Schuchardt, of Goerlitz, Germany, prepares some of the rarer metals, and charges for them the following prices: cerium, 20 shillings per gram; lanthanum, 40*s*.; didymium, 30*s*. These are in globules obtained by electrolysis. Thorium, in powder, is 36*s*. per gram.

Black Stain for Copper.—Deep black is thus obtained upon cleansed copper: Dissolve 3 or 4 oz. of blue ashes, hydrocarbonate of copper, in a sufficient quantity of aqua ammonia; place the cleansed copper in this solution; cold or tepid, it will be instantaneously covered with a fine black deposit. This coat is so thin that burnished articles look like varnished black.

To Varnish Oak.—First rub well with sandpaper the lengthway of the wood, then take about 2 oz. of raw sienna, 1 oz. of vandyke brown (in water-color), mix with some beer both colors to the thickness of ink (if too dark, let down with more beer), and apply with a painter's sash tool brush, softening off while wet with a larger clean brush of any kind, the lengthway of the wood. The colors can be obtained at any respectable painter's shop. When dry give it a thin coat of oak varnish, and do so again after a few days have elapsed.

Emery Belts and Wheels.—Most users of emery belts and emery wheels do not use glue that is thick enough, fearing it may chill before the sand or emery can be spread. In making an emery wheel or belt, if the cloth has never been glued, it should be sized with glue about as thick as lard oil, and allowed to dry thoroughly before applying the glue which holds the emery. Have the emery heated to 200° Fah., and coat the belt or wheel with glue about as thick as molasses and roll it in the hot emery. If a wheel or belt thus treated is allowed sufficient time to become thoroughly dry it will be very serviceable.

To Preserve Orchids.—The *Gardener's Chronicle* states that M. Thuret, the celebrated French naturalist, has found a saturated solution of common salt to preserve orchid flowers in excellent order, even for as long as sixteen years, and to answer much better than spirits of wine. This fact cannot be too widely made known to persons dwelling in foreign countries, who might thus send home specimens of new medicinal or other plants for description. The editor of that journal recommends the use of flat bottles, and the careful arrangement of the specimens, so that it may be possible to examine them without opening the bottle.

To Improve the Appearance of Furniture. Take a soft sponge, wet with clean cold water, and wash over the article. Then take a soft chamois skin, and wipe it clean. Dry the skin as well as you can by wringing it in the hands, and wipe the water off the furniture, being careful to wipe only one way. Never use a dry chamois on varnish work. If the varnish is defaced and shows white marks, take linseed oil and turpentine, in equal parts; shake them well in a vial, and apply a very small quantity on a soft rag until the color is restored; then with a clean soft rag wipe the mixture off. In deeply carved work the dust can not be removed with a sponge. Use a stiff-haired paint-brush instead of a sponge.

Preparation of a Durable Paste.—Max Regensberg recommends the following method for preventing mucilage, starch-paste, glue or gelatin solutions from spoiling. Any of the above-mentioned solutions or pastes, which should have been prepared with hot rain or distilled water, are mixed with a few drops of ordinary commercial silicate of sodium (silicate of soda) two to three drops for every fluid ounce. The preservative having been added, the mixture is well stirred with a wooden spatula. A solution which has already commenced to decompose may be restored by heating it strongly and adding four to five drops of silicate of sodium for every fluid ounce.

Cutting Caoutchouc.—Dip the knife or cork-borer in a solution of caustic potash or soda; this, although the strength matters little, should not be weaker than the ordinary reagent solution. Water is used in preference to alcohol, which evaporates too speedily. When a tolerably sharp knife is moistened with soda lye, it goes through india rubber as readily as through cork; the same may be said of any cork-borer. By this method inch holes may be bored in large caoutchouc stoppers, perfectly smooth and cylindrical. To insure a perfect finish to the hole, and no contraction of its diameter, the stopper should be firmly pressed against the flat surface of common cork till the borer passes into the latter.

EXCHANGES.

Send to W. S. Beekman, 2 Fountain Pl., Roxbury, Mass., for minerals and chemicals; state what you have for exchange; books, microscopes, chemicals and electrical apparatus wanted.

What offers for Household microscope, darning machine, new 7 shot revolver and box of cartridges, small gold watch, violin and case. J. H. Bell, Tarboro, Edgecombe Co., N. C.

A magic lantern with eight slides, original price $6, to exchange for a gun, telescope, good fishing rod, or revolver. John H. Boies, Box 246, Hudson, Mich.

Wanted, scientific books and instruments; please send list and what you want for them. W. A. Brooks, Jr., P. O. Box 122, Salem, Mass.

To exchange, a seven shot Smith & Wesson revolver, 22-100 calibre, in good condition; state what is offered in exchange. W. B. Flausburgh, La Fargeville, N. Y.

For anything relating to drawing or penmanship, will exchange a new book on fortute telling, and a treatise on chiromancy; 1,750 engravings; price $2. W. C. Gamble, Bothwell, Ontario, Canada.

To exchange, a house swing, cost $3, in good order, for a hammock. Henry M. Haviland, 103 Park Pl., Brooklyn, N. Y.

Wanted, a magic lantern good enough for public exhibition; state what is wanted in exchange. G. W. Kessler, Altoona, Pa.

To exchange, a collection of about 125 rare minerals, each encased in uniform box, accurately labeled, classified and numbered, for telegraph sounder, battery, &c., complete, model engine, microscope or offers. Jos. G. Kitchell, 345 Race St., Cincinnati, O.

A horizontal slide valve steam engine and tubular boiler, cylinder 1¼x2½in., with pump and heater all complete, ready to set up and run; worth $25; for type and accessories for job printing, or offers. Geo. L. Lamson, La Fargeville, N. Y.

Wanted, good nickle rim banjo; have barber chair to give in exchange. C. H Lockwood, South Westerlo, Albany Co., New York.

Wanted, works on natural sciences, phrenology, or physiology, loose or bound numbers of monthlies on science or health, etc., small printing press or microscope; for books or lessons in shorthand. H. C. Lucas, Macomb, Ill.

A good philosophy, 393 pp., will exchange for "American Agriculturist," microscope or book on microscopy. J. Y. Mohler, Middlesex, Cumb. Co., Pa.

A rifle (range 60 rods), gold watch and violin; your choice; a galvanic battery preferred in exchange. Jas. M. Ovenshire, Barrington, N. Y.

Wanted, to exchange all the numbers of "The Cincinnati Artisan," for the year 1879, and three beautiful scroll saw designs, for a small but good dark lantern (bull's eye). E. E. Pinkerton, Afton, Union Co., Iowa.

To exchange for other things, one hundred theological (evangelical) and miscellaneous books. E. J. Rich, Brookfield, Mass.

Wanted, a floor-board planer in exchange for scientific books, microscope or micro-spectroscope, etc. Henry A. Sprague, Charlotte, Maine.

Wanted, to exchange two telephones, a B-flat cornet, an aquarium with fountain attachments, for a pair of telegraphs and keys. W. C. Vick, East Ave,. Rochester, N. Y.

For exchange, two Excelsior, No. 2, printing presses; state offers. W. A. Wilcox, Tunkhannock, Pa.

A book, "Fret Sawing for Pleasure and Profit," by H. T. Williams, cost 50 cts., in exchange for a book of sawing patterns, or offers of similar value. S. B. Wilson, Lenoir, N. C.

PUBLISHER'S DEPARTMENT.

Steel Pens.—A pen, in the course of manufacture, goes through twenty-five different processes, takes four weeks to complete, and yet is offered to the general public by the gross box at considerably less than a cent a pen. It is only by manufacturing pens on so large a scale that they can be produced at prices to meet the demands of competition, and it is only by producing articles of unexceptionable quality that such quantities can be disposed of. The largest manufacturers in the United States are the Esterbrook Steel Pen Company, of Camden, N. J., their warehouse being at 26 John street, New York. Their pens are for sale by all the leading stationers in the country.

Object Lessons for Old and Young.—The influence for good which the Exhibitions of the American Institute have exerted upon the young people of New York and neighboring cities, can scarcely be overestimated. Year after year it furnishes to old and young a series of object lessons unequalled in extent and character. Not only do we find a most extensive collection of interesting products, the newest and best of their kind, but we are enabled to see in many cases the actual process of their production; and this, to many young people, is a sight which cannot easily be found elsewhere, for it is only the privileged few who have the *entree* to factories, workshops and laboratories. We know of no place where our young readers can spend a few hours to greater advantage than in the exhibition of the American Institute.

The House-bell of the Future.—When the modern house-bell, with its meandering wires leading through the most crooked by-paths from mistress to servant, was first substituted for the primitive clapping of hands which is still in vogue in the East, what a wonderful improvement it must have appeared! But even the house-bell has its defects, the most obvious and prominent of which is that it cannot serve to convey a message, but merely to summon the messenger. When, therefore, the telephone was invented, it became obvious that this must speedily displace all wire bells, for here we have the means of imparting a message without the necessity of first calling the servant to us. Half the time and trouble is therefore saved, and as the wires for the telephone can be put up along any wall, and may be twisted and turned round any corner, the great trouble and annoyance attending the putting up of bell-wires and cranks, with the accompanying nuisance of having to bore through partitions, is done away with. The expense of the telephone was at first almost prohibitory, but they are now manufactured and sold by such firms as Kent. Woodstock & Co., 25 Congress St., Boston, at such a low rate that any one may have them. The telephone, therefore, may safely be called the house-bell of the future.

INDUSTRIAL PUBLICATION

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. II. NEW YORK, OCTOBER, 1879. No. 10.

French Polish.

HOWEVER much may be said against the brilliancy of French polish and in advocacy of the "dead" finish which of late years has become so fashionable, there can hardly be any question as to the great beauty of a finely finished surface. The grain of the wood comes out so distinctly and beautifully that for ornamental articles, at least, nothing can compare with it. The art is not difficult to learn, though at first the amateur must expect to meet with many failures. There is no secret about the matter, but there is a certain knack which can only be acquired by practice, but which when once learnt is never forgotten. No attempt at scraping, sandpapering or polishing veneered work must be made till the glue is perfectly dry and hard. It should be left twenty-four hours in a warm room at least, and better still if left two or three times as long.

The processes for French polishing vary somewhat according to the nature of the wood. For common work in deal, the wood may be well sized first, then papered with fine sandpaper, and polished.

For mahogany, walnut, and similar porous woods, the pores must be filled by rubbing in, on a roller of old carpet, a mixture of Russian tallow (that is, tallow free from salt) and plaster of paris, well amalgamated—before the fire in cold weather. Russian tallow may be had at most oil shops generally pure enough; but if the presence of salt is suspected, refine it by boiling it in plenty of water, stirring it well, and skimming it. Set it by to cool, and use the cake of tallow which will be at the top.

The more this filling-up process is persevered in, the less will be the subsequent labor in polishing; quite a bright surface should be got up by this alone. The mixture of tallow and plaster may be darkened with red lead for mahogany, or other coloring matter, according to fancy.

This filling is not necessary for boxwood, ebony, or others of the hard woods.

To polish a surface thus prepared, not being hard wood and not in the lathe, take a ball of cotton wool saturated with methylated French polish; cover it with a fold of linen cloth; on the linen cover put with the tip of the finger a drop or two of raw refined linseed oil (not "boiled oil"); get on a good body of varnish by rubbing always one way with circular strokes: be very careful to go over all the ground each time you work round the surface; and do not go over the same spot twice before you have gone over all. The longer this is done the better. Never mind the smears, which, though they look queer, are the very appearance you want at this stage. Having got on a good body, leave your work and take to another piece. It is good to leave it, if convenient, even for a day or two. By the way, shut all doors and windows before you begin. You can't do French polishing in a draft or in a very cold room.

When you resume work, use a mixture of half methylated spirit, or less than half of the spirit when you commence, and put now as little as possible on the wood, covering it with more than one fold of fine linen or cambric. Very little oil, as before —only just enough to prevent the rubber from sticking to the work; go over it lightly, with an easy gentle touch, in circular strokes, all one way. Never mind the smears. When it comes to look something like a good result, which it soon will, you may take out the smears by rubbing up and down with a mere trace of spirit on wool well covered with the linen, but avoid going over the same place twice, and be very light and gentle, or you will remove your polish. Finally, rub it well with a clean wash leather (carefully folded, so as to have no hard crease which will scratch), or an old silk handkerchief, breathing on the work occasionally.

Boxwood, ebony, cocus, etc., may be rapidly polished in the lathe. At first get a body on of polish, and this can be done without using any oil. The work must not be turned round rapidly, but the pulley of the lathe moved slowly by hand; then use your rubber with a drop of oil, and finally, the polish thinned with spirit.

If either on flat or turned work you require a very superior polish, you may remove nearly all the first coat with fine sandpaper, and put it on again, which will not take long, the pores being all filled. Remember that throughout, the oil is only used to prevent the rubber from sticking, and it has to be got out afterwards with the spirit; so never use more than necessary.

In the lathe, when you come to the wash leathers, the work may be driven rapidly. A bit of ebony can be polished in five or six minutes to such a surface that small print can be easily read in it as in a mirror. Don't use your rubbers when they get hard and dry, but nevertheless stick to an old one as long as you can, and if you have to put them by, keep them in a tin box tightly covered.

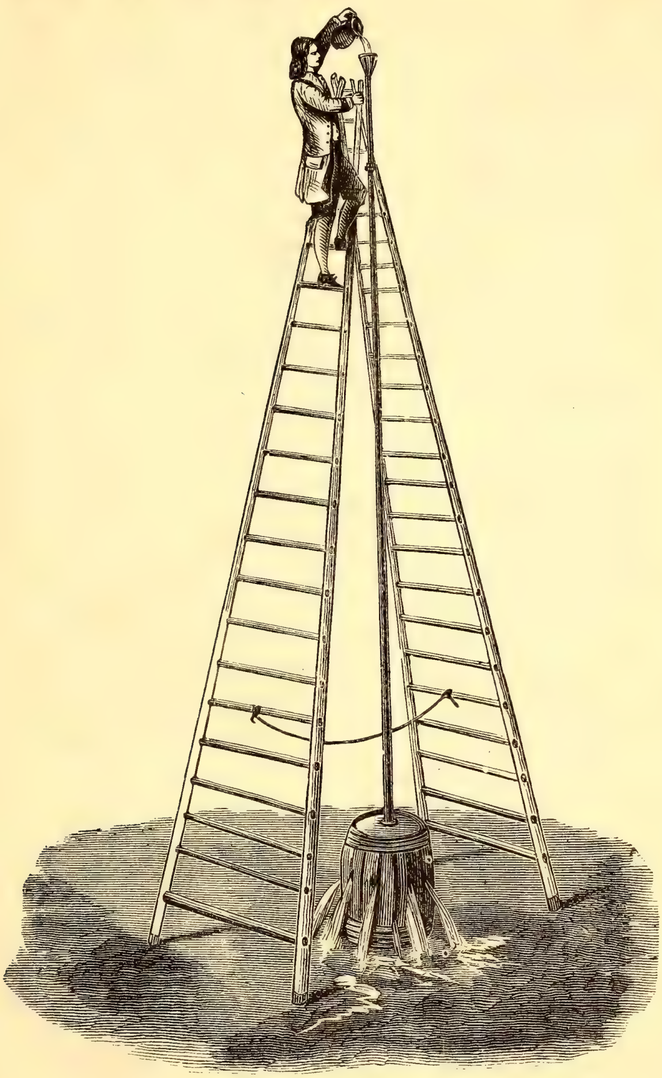
A Lesson in Hydrostatics.

BEGINNERS in science are often frightened with hard words and think that because a subject has a long, hard name like hydrostatics, therefore, it can have no relation to ordinary everyday occupations. But just as the countryman in the French play had talked prose all his life without knowing it, so every good housekeeper concerns herself with hydraulics, hydrostatics, pneumatics, etc., without being aware of the fact. It will not be difficult to find many illustrations of hydrostatics in ordinary household work. But first of all let us examine the engraving on the opposite page, and learn what it teaches us.

The experiment which this figure illustrates is one that it is not difficult to repeat. A good stout barrel, known to be watertight, has a long pipe secured to its head as shown in the figure. The cask may now be filled with water until the liquid stands two or three feet high in the tube, and it will then be easy to see whether or not the cask leaks. If everything is sound, pour another pitcherful of water into the tube, and unless the cask is very much stronger than those usually made, the hoops will burst and the water pour out of the openings between the staves.

The astonishing feature of this experiment is the very small weight of water that

is required to burst the cask. A few pounds at most are all that need be used, and strange to say—*the larger the cask the more easily will it burst!* The latter is a exerts a pressure of so many pounds per square inch for every foot in height that it stands. If this pressure be 10 lbs. on each square inch and there are 10 square



A LESSON IN HYDROSTATICS.

fact that very few can believe until after they have carefully studied the subject, but it is very easily understood when the correct view of the matter once presents itself to the mind. The water in the tube inches then the whole pressure is 100 lbs; if there had been 100 square inches the pressure would have been 1,000 lbs. Hence the greater the number of square inches the greater is the pressure on the vessel,

and therefore, the larger the cask the more easily can it be burst.

A few days ago a very striking illustration of this principle came under our observation. A lady who had just received some new cider thought she would like to bottle some. She had seen cider successfully kept in small bottles—why would not a large demijohn be stronger and better? So the demijohn was filled with cider and the cork tightly inserted. In a few minutes the cider had worked so as to create quite a pressure within the vessel and out flew the large cork with a loud report. This, however, was easily remedied. The cork was driven in again and tied tightly down. Before long, however, another report was heard, and this time the demijohn itself flew to pieces and the cider was scattered over walls, ceilings and carpet.

Now, if instead of one large demijohn, this lady had taken a dozen small bottles, it is not likely that the cider would have burst them. Numerous illustrations of this principle are seen all around us. A small gun, with sides not one quarter the thickness of boiler-plate, will resist a pressure which would completely wreck a large steam boiler.

Scroll Sawing—IV.

BY F. T. HODGSON.

AT this stage, the young student will think himself sufficiently advanced to make a bracket; but I would advise him not to attempt it just yet, as failure to make a neat one will surely be the result; and failure is always discouraging to a beginner. In place of making a bracket, it would be better to practice cutting out letters similar to the ones shown below. They can be cut out of the sides of cigar boxes until a state of proficiency is reached that will warrant an attempt being made in more valuable woods.

If letters similar to the ones shown, are made of thin holly, and skillfully cut out, they may be put to many useful and ornamental purposes. For instance, take a piece of fine scarlet or crimson cloth and use it for a back ground, then take clean cut letters and glue them neatly on the cloth, forming the motto, "Home Sweet Home," or any other appropriate sentiment that may be fixed upon. When this

A B C D E F G H

is done, design a neat border with corresponding corner ornaments, cut out of holly and glue round the cloth, mitering them properly at the corners. This will make an ornament far more handsome if skillfully done than any bracket that could possibly be made at this stage. The fancy can roam a little even in the cutting of these letters, for the H, S, H, may be made larger and more ornamental than the intervening letters, and a spray of ivy or maple leaves may be interwoven through the whole motto; but this can only be done successfully by a good hand.

Letters may also be employed when neatly cut, on glove-boxes, work-boxes, and dozens of other things; and I can assure the pupil that no practice will give him such a mastery over the saw as that of cutting letters of various styles. The letter S contains all the curves, kinks, and angles, that will ever be met with in the whole range of fret-sawing.

A bracket may now be attempted—a small one first—it would be better to make it of some cheap material, such as pine, walnut, or white wood. A simple design, similar to Fig. 17, will be the best to adopt

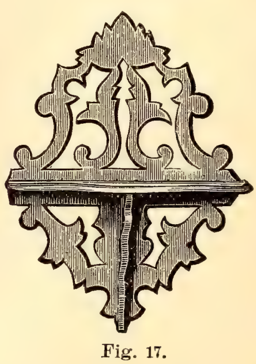


Fig. 17.

at first, bearing in mind to make all the inside cuts first. Of course, it will be necessary to bore a small hole through the bracket in every part that requires to be removed from the inside. These holes are

made to admit the blade of the saw to pass through.

If the pupil is a pretty fair hand to draw, he may be able to make his own designs, if not, it is better to purchase them in sheets, as they can be obtained at very reasonable rates; and where it is desirable to preserve any particular design, it may be done by first pasting the original design on a thin piece of stuff, then taking another piece of thin stuff and inserting a flat piece of zinc between them and sawing all three together, being very careful to follow the lines of the design closely, for any defect in the sawing will be a permanent one in the pattern. There will be no difficulty in cutting the zinc; use a No. 3 saw, feed slowly and you will be astonished at the result. This is the best way I know of for saving a valuable pattern, as the zinc will not break or change its shape. When the sawing is finished, there will in all probability be a few rough edges and crooked corners; to remedy these use your files and sand paper, being careful not to file down any of the angles. The under edges will be somewhat ragged, but a proper application of sand paper will make them smooth.

The next thing will be to put the work together, which, with some young folks, is a more difficult job than to saw it, but any one having the smallest amount of constructive ability, will be able to put the work together without much trouble. If the bracket is intended to carry books or other heavy articles, it is always better to put it together with screws and glue; if, however, light articles only are to be placed on the shelf, brads and glue will be all that will be required to fasten on the shelf and sustaining bracket. The shelf and sustaining bracket should always be thick enough to admit of small screws being used in them to fasten them together.

Fig. 18 is a more elaborate bracket than the preceding one and will require more care in cutting, but the pupil, after satisfactorily finishing the bracket shown at Fig. 17, can safely be trusted to saw this or any similar one. Further examples of brackets are unnecessary, as these cuts are too small to be of much service to the amateur without being enlarged; and are only intended to aid him in choosing such designs as may be useful to him in mastering the saw.

It is supposed now, that the pupil is fully competent to cut any kind of bracket, therefore, it is time he should try his hand

Fig. 18.

at something else; so at Fig. 19 he is shown a small frame for a photograph, which is to be cut in holly or walnut; it is

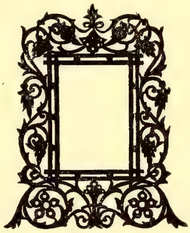

Fig. 19.

very neat and will try the patience and ingenuity of the sawyer, but perseverance and love of the work will soon overcome any little difficulty that may occur.

In the next issue I will take up the subject of inlaying, as the pupil is now sufficiently advanced to make an attempt, with fair chances of success, of doing some handsome work in this department.

Straight Edges.

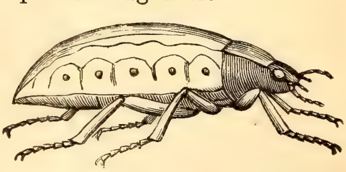
PERFECT accuracy of outlines is of the highest importance in the construction of all machines and parts of machines. The amount of care requisite to the production of a good straight edge, or surface plate, is very great. The means by which this accuracy is attained are somewhat as follows:

Three pieces of mahogany, or other hard wood, about three feet long by a quarter inch thick, are planed up as truly as possible, the planed surfaces of all three being from time to time applied to one another,

in order to judge of the trueness to which the surfaces are being reduced. When any one of three prepared surfaces will lie on the prepared surface of either of the other two without allowing any light to pass through the line of junction, the edges may be considered sufficiently true to admit of their being used in the production of a metallic straight edge. To this end three similar strips of steel, of the size desired, are smoothed or cleaned upon their sides on a grindstone or with a file. They are then laid one upon the other, and a hole drilled at each end, a rather tight-fitting pin or rivet being run through each hole to keep the three bars together. In this state they will appear as one thickish bar. The compound bar being placed in the vice and clamped on each side with sheet lead or zinc, the edges are filed level, beginning first with a rough file, and gradually increasing in fineness. Every now and then the edge being produced is tested against one of the wooden edges above described, which should be previously rubbed over with red chalk, etc., to render prominences visible. When the eye no longer detects any differences in level on the application of the wooden straight edge, the steel pieces are to be removed from the vice, and pins extracted. They must now be tested against one another, until, by careful filing and repeated comparison with one another, it is found that the edges of all three will unite closely without any irregularity being perceptible. A good way of ascertaining whether any such exists, is to place two edges in contact and rub them together with some force; the prominent portions will by this treatment be somewhat burnished, and will render themselves apparent by their superior lustre. The reason why three edges should be prepared simultaneously will be sufficiently evident on reflection. It will be readily understood that if A and B were two strips of steel, that A might be slightly concave and B correspondingly convex, without the eye being able to detect any fault, as no light would pass: but if a third strip, C, having the same convexity as B, were applied against the latter, the fault would immediately become apparent, and on correcting the faults of B and C, and applying them to B, the concavity of this latter would also be rendered visible.

How Insects Breathe.

THE fact that we ourselves, and all the larger land animals with which we are acquainted, breathe through the mouth and nostrils, has led most people to think that insects too breathe through the mouth. Ask those who have not made a special study of insects, how the fly breathes, or, rather, at what point of its body it takes in the air, and it is ten chances to one that you will be told that it breathes through the mouth. The insect, however, does not breathe through the mouth, but through a series of openings placed along the side. In many flies and small insects these openings are invisible to the naked eye, but in some of the larger beetles and in most caterpillars they can be readily distinguished without the aid of a microscope. The common cockchafer or May-bug in the larval or caterpillar state shows these breathing pores or spiracles very clearly. In the white caterpillar they appear as a row of dark brown dots down the side. When viewed with a low power (25 diameters) these dots are seen to be oval openings, partially shielded from dust, etc., by minute hairs. In the beetle their position is shown in the engraving, the hard wing cases having been removed so as to uncover them. They can be clearly seen with a pocket magnifier.



BREATHING PORES OF BEETLE.

These spiracles form very curious and interesting objects when mounted for the microscope. The skin of the caterpillar may be soaked in weak potash solution so as to remove the grease and render the substance transparent. It should then be washed in water, afterwards in the strongest alcohol, and after that it should be soaked in spirits of turpentine. When

thoroughly saturated with the latter it should be mounted in Canada balsam.

From caterpillars it is easy to procure not only the spiracles but the connected air tubes or tracheæ. These form very beautiful objects when perfectfy dissected and well displayed. The best method of preparation is to slit the caterpillar open along the under side and soak it in acetic acid. After a day or two the entire system of tracheal tubes may be separated by means of fine needles, and after washing with water, and soaking in alcohol and turpentine, they may be mounted in balsam—or after washing with alcohol they may be mounted in glycerine.

Notes on my Cabinet.

THE microscope is not only a means of education and a tool for accomplishing valuable practical work, but, also a source of great pleasure and amusement from the endless variety of beautiful and curious things which it enables us to examine. And, although many scientific men look down upon such a use of the instrument, to my mind it is one of great value and usefulness. An evening spent over the microscope, even by those who have but little scientific knowledge, tends to elevate and improve.

Nothing tends so much to enhance the pleasures of such an evening as a good supply of interesting slides or objects. They need not be very costly or even of much scientific value; if they show the objects well and bring out clearly a few important points, it is all that is required. But, in order to get the greatest enjoyment out of such an evening, it is necessary that we should have something which will exercise our minds as well as our eyes.

I make no pretensions to being a microscopist, and the instrument which I use would probably be ridiculed if introduced at any of our modern microscopical exhibitions. But, by means of it I have been enabled to give a great deal of pleasure to friends, young and old, and, perhaps, a few leaves from my experience may not be unacceptable to readers of the YOUNG SCIENTIST.

Some objects can only be kept on hand when carefully mounted on glass slips. This is the case with different kinds of blood and with all objects which are difficult to procure, and which require much time for preparation. But I have always found that the objects which give the most pleasure to a gathering of a few friends are not the finely mounted slides but those common objects which are easily found, easily prepared, easily mounted, and easily shown. A few evenings ago some friends called at my house, and out came the inevitable microscope. I first showed them some slides of diatoms and other scientific things which pleased them much, and greatly excited their wonder when they came to see that the large and elaborately carved shells which were so beautiful under the microscope were entirely invisible to the unassisted eye. But, after all, there was a kind of feeling as if the microscope had *made* these things, not as if it merely enabled us to see things that were already in existence and which merely required keener vision to render them sensible. After a while, however, a lull took place in the exhibition, and the conversation wandered off to other matters. One lady incidentally mentioned that she had purchased, very cheaply, some material which was warranted all wool, but which she feared was partly cotton. As she had the stuff with her I suggested that it would be very easy to settle the question by an appeal to the microscope. So a little of the fabric was cut off, placed on a slide, and teased out with common needles stuck in pine handles. It was then moistened with a little glycerine and water and covered with a thin glass. On placing it under the microscope it was at once seen that the material was, at least, three-fourths cotton, and this was so obvious to every one that looked at the object, that the utmost surprise and pleasure was shown by all. No diatom, however beautiful, could have excited the same interest as these few fibres of cotton and wool.

In my next letter I will tell my readers something more of these appearances and describe to them the best way of examining such objects.

O. W.

Too Much Philosophy.

SOME people are always ready with a theory for every phenomenon. In general they depend upon "electricity" for a solution of any problem which presents itself, but as this has of late been run into the ground, they resort to new spectroscopic theories for the heat, or in severe winters to gulf-stream theories for the cold. A gentleman who had a great contempt for such theorists, and who expected a visit from some of them, had in his garden one of the well-known carboys, or globular bottles of dark glass, in which sulphuric acid had been kept. Such bottles form a mirror in which the surroundings are seen reflected on a very small scale, and might be looked upon by some as heat concentrators. The bottle was lying on the ground in the sunshine, and the professor made his guests observe that singularly the upper side, exposed to the sun, was not so hot as the lower side. At once a few of the learned friends said that of course this must be so, because the dark glass was very transparent to the caloric rays, which, therefore, did not heat it, but passed through and were absorbed under the bottle by the ground, which then heated the under side of the bottle by conduction. Others held that the form of the bottle was the cause; the upper side being convex, distributed the rays by reflection, while the under side being struck by the rays on its concave surface, concentrated them. A few other theories were propounded, to none of which our professor agreed, when finally his friends insisted that he should give an opinion as to the cause of the bottle's being hotter below than above. He said that he had turned it round, upside down, just when they entered the garden.

Editorial Notes.

To Our Subscribers.

THE confusion attendant on certain changes in our location and business, and the failure of certain parties to furnish articles and illustrations for which we had contracted, caused some delay during the summer months which proved very annoying to our subscribers and to ourselves. There are two numbers more required to complete the volume, and they will be issued without delay. Our arrangements now are such that the YOUNG SCIENTIST will be issued hereafter regularly and promptly. It is the only journal of the kind in the world, and we hope our young friends, and old ones too, will help us to make it better. This can only be done by aiding us to secure as many new subscribers as possible. Let each boy and girl try and get us one new subscriber and the YOUNG SCIENTIST for 1880 will be a glorious success. And to encourage them to do this we would call attention to the liberal premiums which we offer.

Who Wants a Knife?

EVERY boy wants a good knife and no lady's work-basket is complete without one. We have just purchased, at a great bargain, a few very excellent pocket knives of Sheffield manufacture. We have tried these knives and they are really good, notwithstanding the fact that we bought them so low that we can give one to each of our subscribers who will send us $1.00 for his own subscription and that of some one not now a subscriber.

These knives are of three different kinds. One is for boys; it is a stout knife with two blades and buck horn handle; one blade is large and strong for whittling; the other is small. The second knife is lighter; it has a large and a small blade, and the handle is of dark cocoa; it is an excellent knife for the vest pocket and for light work. The third knife is quite small; it has two blades and a white handle with name plate on it. It is a lady's knife rather than a boy's. Those who secure one of these knives as a premium can take their choice of any of the three.

In addition to these knives we have the following, which are marvels of cheapness. No 1 is a sportsman's knife with stag handle. It has the usual blades with corkscrew, picker, gimlet, etc. Such a knife usually sells for $1.50, and we offer it to any one who will send us three subscriptions—two of which must be new names.

No. 2 is a very handsome knife with tortoise-shell handle and three blades. It is specially suited for ladies, and is a very beautiful article. A cutler on Broadway asked us $1.75 for a similar knife. We offer it for 5 subscribers, four of whom must be new.

No. 3 is a very pretty penknife with two blades—the handle inlaid with mother of pearl. This we offer for 3 subscribers—two of whom must be new.

Designs for Scroll-Sawyers.

MR. HODGSON, whose admirable articles on scroll-sawing are now in course of publication in the YOUNG SCIENTIST, has prepared for us a series of seventeen designs covering a great variety of subjects suitable for Christmas presents and ordinary articles of household ornament and utility. These designs we have had photo-lithographed and printed on two large sheets. They are full size and embrace over forty different pieces. Knowing that this set must have a large sale, we have placed the price at 25 cents for the set, or a cent and a half for each design. We know of no designs equal to these which can be had for less than five, ten, or twenty cents each.

To any boy or girl who will send us a new subscriber, (together with their own subscription) we will send a set of these designs free. The subscriptions may be for 1878, 1879, or 1880. Remember, one of the subscribers must be new. It will not do to send a renewal of the subscription of an old subscriber.

Relacquering Brass.

Articles which have been lacquered before are easily cleaned by boiling them in pearlash, when the old lacquer will be destroyed, though it will perhaps still lie upon the surface as a whitish kind of varnish. To remove this, and restore the articles to their proper color, let them be soaked in a solution of aquafortis and water, and then suffered to remain some hours, according to circumstances. The acid eats away the outer coat, leaving a bright surface beneath. The goods are now put in bran, and then shaken about to dry and clean them, when they will be ready for lacquering again, which is done as follows, in two ways, called cold lacquering and hot lacquering: by the former, a little lacquer being taken on the brush (a common camel hair varnish one), it is laid carefully and evenly on the work, which is then placed in an oven or on a hot stove; the heat from this continued only a minute or two is sufficient to set the lacquer, and the work is finished. By the second method the work is heated first to about the heat of a flat iron as used by the laundress, and the lacquer quickly brushed over it in this state, the work being subjected to the oven for a minute or two afterwards, or not, according to the pleasure and judgment of the lacquerer. The article, if very small, will require this, because it will have parted with most of its heat in laying on the lacquer; if heavy it will retain sufficient to perfect the process. The greatest difficulty is to know the exact degree of heat, and this cannot be attained except by experience, so different is the nature of the materials, the quality of different lacquers, and the effect to be produced. The following recipes for lacquer have been found by experience to give good results and a considerable range of color. 1. Seed-lac, dragon's blood, annatto, and gamboge, of each 4 ounces; saffron, 1 ounce; spirits of wine, 10 pints. 2. Turmeric, 1 pound; annatto 2 ounces; shellac and gum juniper, of each 12 ounces; spirits of wine, 12 ounces. 3. Seed-lac, 3 ounces; amber and gamboge, of each 2 ounces; extract of red sanders, ½ drachm; dragon's blood, 1 drachm; saffron, one-fifth drachm; spirits of wine, 2 pints 4 ounces. 4. Turmeric, 6 drachms; saffron, 15 grains; spirits of wine, 1 pint 4 ounces; draw the tincture; add gamboge, 6 drachms; gum sandarac and gum elemi, each 2 ounces; dragon's blood and seed-lac, of each 1 ounce. 5. Put into a pint of alcohol, 1 ounce of turmeric powder, 2 drachms of annatto, and 2 drachms of saffron; agitate during seven days, and filter into a clean bottle: now add 3 ounces of clean seed-lac, and agitate the bottle every day for fourteen days. 6. *Pale brass lacquer:* Alcohol, 4 gallons; cape aloes (small), 6 ounces; pale shellac, 32 ounces; gamboge, 2 ounces; dissolve.

Autumn Leaves.

America is unrivalled for the gorgeous colors of her autumn foliage, and many of our young readers, no doubt, take great pleasure in collecting autumn leaves, pressing them and arranging them in bouquets. The great difficulties to be contended against are that leaves are apt to curl and to become so brittle that they break very easily. We give the experience of two correspondents of the *Household* who seem to have had specially good success.

One says: "Press the leaves between the pages

of an old book, allowing them to remain until perfectly dry. Then rub a little boiled oil over the surfaces of the leaves, and place them to dry where the dust will not settle on them. Boiled oil is preferable to wax because it renders the leaves tough and flexible instead of brittle, while it gives them the same beautiful glossy appearance. Mine that were prepared in this manner last autumn are still on the walls, mementos of the dear mother that placed them there, who has since been summoned to that land where all that is beautiful is unfading."

The other gives her experience as follows: "I press them two weeks perhaps, or until thoroughly dry; then varnish them on the right side only, and lay on a board in a dark room to dry. I never have them curl or break when thus prepared. Ferns, when pressed, become beautiful ornaments in a few days, (do not press them too long or they become brittle,) and then paint them with a mixture of paris green and varnish; I wish you could see my wreath of autumn leaves and ferns."

Those who use Paris green for this purpose must be cautioned that it is a deadly poison. Never work with this substance in powder as the fine dust, when inhaled, may give rise to serious trouble. If mixed with oil or varnish so as to be moist there is less danger.

Punching Holes in Straps.

Boys who have occasion to punch holes in their skate straps, or straps for carrying books, etc., will find the following hints valuable:

The punching of holes through the various straps of harness, for buckle tongues, and for attaching the buckles, is a matter of considerable importance, and does not, as a rule, receive the attention that it should. The old method, of punching them from the upper or grain side of the leather, has been generaly abandoned by the manufacturers of fine work, it being deemed injurious to the wear of the leather. The principal objection arises from the liability of the grain of the latter to crack from the strain of the buckle-tongue, and to be the cause, eventually, of the leather tearing, as it causes such a crease where the tongue catches, that it injures the texture of the leather, and makes it tear the hole more or less In addition to this, if the leather is very strong, the tongue of the buckle is sure to bend out of shape. All these objections can be obviated by punching from the under or flesh side of the strap, and by using a punch, the long sides being parallel with the length of the strap; the punch should be set at an angle of about twenty degrees, cutting the hole at such an angle that the buckle-tongue will rest in it without throwing any strain on the inside of the leather. Some object to punching the hole from the under side on account of its forcing the grain out, and thus disfiguring the outside edges of the hole. This can be corrected, however, by driving the punch through the hole from the outside, which will cut away the slightly turned edge of the grain, and set it down smooth and clean. It is not necessary, however, to re-punch any holes except those that will be exposed when the harness is complete. Punches should be as thin as possible, as the extra thickness of the metal strains the leather.—*Harness Journal.*

Call for Telephone.

A correspondent of the *Scientific American* gives the following method of making a call for a string telephone. Suspend the telephones at each end, so that the line string (the string connecting the diaphragms) may be kept tightened. and free to transmit vibrations from either end, Now rub some resin on the line string at each end; and when you wish to signal the other, rub along the resined part of the string, and quite a loud noise will be heard in the telephones at each end, sufficient to be heard anywhere in the room. It is on the principle of the boy's "rooster," consisting of a resined string passed through one end of a tin can. Petroleum may be used instead of resin with equally good results. This kind of call does away with electric bells and other contrivances for acoustic lines. If ferrotype plate and fine wire take the place of the parchment diaphragm and strings, the same call may be used by fixing to the wire a piece of resined string, the call being effected as before by rubbing on the string.

To Imitate Japan-Work Boxes, etc.

A very effective style of ornamenting cabinets, window boxes, tables, etc., is that by which the figures of the design are made to stand out in relief upon a black or coral ground, afterward highly polished like Japanese lacquer-work.

A preparation is first made by dissolving the best white beeswax in spirits of turpentine until it is of the thickness of copal varnish. This may be kept in a bottle until you are ready to begin the work, when you may pour out a small quantity and mix into it a little flake-white sufficient to give it a body. Now, with a fine sable pencil, trace accurately the design on the white wood, which has been first made very smooth and clean, and go over every part of the pattern, leaving only the ground-work untouched. When this is well dried, mix ivory-black with parchment size, thus forming a very black kind of paint. Go over the entire surface with this paint, or, if it is intended to give it a coral-col-

ored ground, use the sealing-wax varnish made by dissolving red sealing-wax in spirits of wine. Let the whole get thoroughly dry; and if it is not well covered give it another coat.

When this is dry, let the whole work be brushed with a bristle brush dipped in spirits of turpentine, and rubbed pretty hard until the parts covered with the white mixture are left bare. The designs first traced will now become visible, with sharp, clear outlines marked on the black or red ground, and will look very handsome. It must then be varnished with white varnish, and rubbed down with pumice powder until very smooth.

Practical Hints.

Removal of Iron-stains from Linen.—"Salts of tin" are said to be better for this purpose than oxalic acid.

Shaping Soft Rubber with a File.—Prof. Morton, of the Stevens Institute, states that he finds the ordinary thick sheet rubber, used in making up lantern tanks, and for many similar purposes, may be readily dressed into an exact shape with a file, if only it is supported by being clamped between plates of wood or metal in a vice. The file is used dry, and in all respects as in working on wood or metal.

Green Bronze.—Dissolve 2 oz. of nitrate of iron, and 2 oz. of hyposulphite of soda, in 1 pint of water. Immerse the articles in the bronze till of the required tint, as almost any shade from brown to red can be obtained; then well wash with water, dry, and brush. One part of perchloride of iron, and two parts of water mixed together, and the brass immersed in the liquid, gives a pale or deep olive green, according to the time of immersion. If nitric acid is saturated with copper, and the brass dipped in the liquid, and then heated, it assumes a dark green. If well brushed, it may be lacquered with pale gold lacquer, or else polished with oil.

Waterproof Dressing for Leather.—The Boston Laboratory gives as a waterproof dressing for boots, shoes and leather the following: Lard oil, 100 parts; paraffin, 50 parts; beeswax, 5 parts. Gently warm the oil and in it dissolve the paraffin and wax. If too hard, use a little less wax. Any disagreeable smell may be removed by a few drops of oil of sassafras. The wax prevents the crystallization of the paraffin, and the oil causes the whole to become a paste of the consistency of tallow. The dressing fills the pores of the leather, does not dry, but keeps the leather soft and pliable. Boots and shoes to which the dressing is applied may be polished, using ordinary blacking, which is not the case with most dressings containing oil or grease.

Waterproofing Linen.—Professor Kurr gives the following directions for this purpose: Pass the linen first through a bath of one part sulphate of alumina in ten parts of water, then through a soap bath, of which the soap is prepared by boiling one part of light-colored resin and one of crystalized carbonate of soda with ten parts of water until the resin is dissolved. The resin soap thus formed is to be separated by the addition of one-third of common salt. In the soap bath the resin soap is dissolved, together with one part of soda soap, by boiling it in thirty parts of water. From this bath pass the articles finally through water, then dry, and calender. Made-up articles may be brushed with the solutions in succession, and be rinsed in the rain. Wooden vessels may be employed.

Working Ash.—Steam is the ordinary means used to soften ash, but when it is practicable, boiling in water is the best. The chief thing is to have the right kind of ash, as some kinds bend and others do not. One tract of land may furnish the best of ash, while another, lying close by and having just as good a soil, may produce only an inferior quality. The timber must be heavy and tough, and cut from good trunks. No matter if it has been cut and dried three years. A splinter of this quality of ash can scarcely be torn off, and runs the whole length of the wood before it ceases. Half an hour's boiling is sufficient to soften a piece of wood six centimeters thick. When the wood is taken out of the kettle, put it in the brace, screw and wedge it in the desired form without relaxing, and let it cool a few hours. After the wood is thoroughly dried in the brace, unscrew it and take out the wedges; it will always then retain its form.

EXCHANGES.

Unmounted objects ready to mount, including diatoms, spicules, sections, foraminifera, polycystina, starches, insects, algæ, zoophytes, etc., for other mounted or unmounted objects. S. N. Hardy, Victoria, Cass Co., Neb.

Bird's eggs wanted. Have in exchange old U. S. coins and other articles. Address E. W. Humphreys, Woodstown, N. J.

Wanted, Scott's revised list of all postage stamps and stamped envelopes, cost two dollars and a half; for sixteen numbers Magazine of Art, cost four dollars; or books. E. H. Jenkins, Rockland, Mass.

Wanted, good illustrated works on entomology and ornithology; also specimens of natural history, and curiosities for a collection; stuffed birds given in exchange. Geo. C. Jones, Brookfield Center, Fairfield Co., Connecticut.

A number of magic lantern slides wanted; state what is wanted in exchange; will give a good trade. Samuel J. Jones, Box 137, Oxford, N. C.

Wanted, good telescope, 2 to 3½ inch aperture; state what is wanted in exchange. Edward B. Porter, Indiana National Bank, Indianapolis.

Wanted, a good wood lathe, or encyclopædia, or other good books and tools; in exchange for a Bickford Knitting Machine complete; make offers. F. M. Snyder, West Dryden, Tomp. Co. N. Y.

Back numbers of Young Scientist for 1878, a telegraph instrument worth $10, and two books on phonography, (Mrs. Burn's Text-Book and a reader), worth $1.50, in exchange for geological specimens, scientific books, or offers. Robt. E. Stackpole, 2 Varick Place, N. Y. City.

Practical instruction in Takigrafy, or Lindsley's Phonetic Short-Hand, will be given in exchange for good books; a microscope, or guitar worth from $5 to $10. Takigrafer, Box 150, New Haven, Oswego Co. New York.

$22.00 telescope, orchestra B-flat cornet. 5 crooks, and box, Fleetwood scroll saw with boring attachment and 2 doz. saws, cost $26; exchange for printing press and type. Manager W. U. Tel. office, Lanesboro, Susqa. Co., Pa.

Send to W. S. Beekman, 2 Fountain Pl., Roxbury, Mass., for minerals and chemicals; state what you have for exchange; books, microscopes, chemicals and electrical apparatus wanted.

What offers for Household microscope, darning machine, new 7 shot revolver and box of cartridges, small gold watch, violin and case. J. H. Bell, Tarboro, Edgecombe Co., N. C.

A magic lantern with eight slides, original price $6, to exchange for a gun, telescope, good fishing rod, or revolver. John H. Boies, Box 246, Hudson, Mich.

Wanted, scientific books and instruments; please send list and what you want for them. W. A. Brooks, Jr., P. O. Box 122, Salem, Mass.

To exchange, a seven shot Smith & Wesson revolver, 22-100 calibre, in good condition; state what is offered in exchange. W. B. Flausburgh, La Fargeville, N. Y.

To exchange, a house swing, cost $3, in good order, for a hammock. Henry M. Haviland, 103 Park Pl., Brooklyn, N. Y.

Wanted, a magic lantern good enough for public exhibition; state what is wanted in exchange. G. W. Kessler, Altoona, Pa.

A horizontal slide valve steam engine and tubular boiler, cylinder 1¼x2½in., with pump and heater all complete, ready to set up and run; worth $25; for type and accessories for job printing, or offers. Geo. L. Lamson, La Fargeville, N. Y.

Wanted, good nickle rim banjo; have barber chair to give in exchange. C. H Lockwood, South Westerlo, Albany Co., New York.

To exchange, a collection of about 125 rare minerals, each encased in uniform box, accurately labeled, classified and numbered, for telegraph sounder, battery, &c., complete, model engine, microscope or offers. Jos. G. Kitchell, 345 Race St., Cincinnati, O.

For anything relating to drawing or penmanship, will exchange a new book on fortune telling, and a treatise on chiromancy; 1,750 engravings; price $2. W. C. Gamble, Bothwell, Ontario, Canada.

Wanted, works on natural sciences, phrenology, or physiology, loose or bound numbers of monthlies on science or health, etc., small printing press or microscope; for books or lessons in shorthand. H. C. Lucas, Macomb, Ill.

A good philosophy, 393 pp., will exchange for "American Agriculturist," microscope or book on microscopy. J. Y. Mohler, Middlesex, Cumb. Co., Pa.

A rifle (range 60 rods), gold watch and violin; your choice; a galvanic battery preferred in exchange. Jas. M. Ovenshire, Barrington, N. Y.

Wanted, to exchange all the numbers of "The Cincinnati Artisan," for the year 1879, and three beautiful scroll saw designs, for a small but good dark lantern (bull's eye). E. E. Pinkerton, Afton, Union Co., Iowa.

To exchange for other things, one hundred theological (evangelical) and miscellaneous books. E. J. Rich, Brookfield, Mass.

Wanted, a floor-board planer in exchange for scientific books, microscope or micro-spectroscope, etc. Henry A. Sprague, Charlotte, Maine.

Wanted, to exchange two telephones, a B-flat cornet, an aquarium with fountain attachments, for a pair of telegraphs and keys. W. C. Vick, East Ave,. Rochester, N. Y.

For exchange, two Excelsior, No. 2, printing presses; state offers. W. A. Wilcox, Tunkhannock; Pa.

A book, "Fret Sawing for Pleasure and Profit," by H. T. Williams, cost 50 cts., in exchange for a book of sawing patterns, or offers of similar value. S. B. Wilson, Lenoir, N. C.

PUBLISHER'S DEPARTMENT.

Amateur Printing.—Although the art of printing, in its higher departments, is one of the most difficult and exacting, nothing is easier than to turn out passable work, and this, too, with presses which at first sight would seem to be incapable of such results. With the small printing presses which are now so numerous in market, it is quite possible to turn out cards, labels, and work of that kind quite as good as the ordinary work of the job printer. And it is not difficult to learn how to do it Amateur printing is perhaps one of the most fascinating and useful of the many pursuits to which young people devote themselves. And it is a wonderful educator. Nothing teaches a boy how to spell and punctuate like the printing press. In addition to all which it is a profitable amusement, for we have known many boys who keep themselves liberally supplied with pocket money by means of their little printing presses. Those who desire to set up an amateur printing office would do well to send to John Metz, 32 Beekman St., N. Y., for a copy of his catalogue, and if they are in town it would be advisible for them to examine his stock.

HOME ARTS.

VOL. III. NEW YORK, JANUARY, 1880. No. 1.

Home-Made Telescopes and Microscopes.—I.

THERE is probably no art that gives so much pleasure to the young beginner, or that excites so much wonder and applause amongst his friends, as that of making optical instruments, and the foundation of this art is the ability to work glass into the various forms that are required. The conversion of a piece of glass, which has perhaps been thrown into the ash box as useless, into an instrument which will increase our power of seeing things twenty or even fifty times, is a feat which any smart boy may accomplish. Such a magnifier or microscope will afford a great deal more pleasure than can be obtained from a far better instrument which has been purchased, and when the skill which has accomplished this simple undertaking has been so far improved that microscopes and telescopes of fair quality are the product of one's own labors, we feel that the result more than pays for all the labor and study that has been expended.

To most persons the construction of a microscope or a telescope seems to require wonderful skill and a very long course of training, but while this may be true in regard to the very highest departments, it is not true of ordinary optical work, very much of which is performed by boys and girls. It does not require any extraordinary mechanical genius or any very expensive tools to make a microscope which will show the most beautiful of the ordinarily invisible objects about which we hear so much. Neither does it require a long apprenticeship or very elaborate tools to enable an earnest lad to make a telescope which will show the moons of Jupiter, the moon-like phases of Venus, or even the rings of Saturn. The construction of a microscope or a telescope which will equal those turned out by famous makers will, of course, tax his utmost efforts, and probably be far beyond

his reach, but there is open to him a field wide enough and useful enough to employ many years, and yield results worth all the time and trouble required.

In the directions which follow we have drawn not only from our own experience, but from the writings of Brewster, Imison, Holtzapffel, Wenham, and others. Modern works on optics give no directions about the mechanical construction of the different instruments used, and the student who tries to pick up information from books will find very little upon the subject. The older writers gave directions which, for the day in which they were written, were very complete. We have now before us a very elaborate work—over two hundred years old—in which the grinding of lenses is very fully described and illustrated. In this book we find a description of a binocular microscope and directions for what in modern times is known as the *local polishing* of lenses—things which are supposed to be of very recent origin. Imison, in his "School of Arts," gives some directions for lens-making, and Brewster, in his edition of Ferguson's "Lectures on Mechanics," tells how to grind lenses and specula. The most complete treatise on the subject, however, is that of Holtzapffel, who, in the third volume of his "Mechanical Manipulation," gives a very full account of the grinding of glass for optical purposes, but the optical part of the subject he does not touch upon. The most precise directions for making objectives, prisms, etc., have been given by Mr. Wenham in the *Monthly Microscopical Journal.* Like all the writings of this gentleman they are thoroughly accurate, minute, and practical. They have recently been republished by Dr. Beale in his book, "How to Work With the Microscope," and we propose to embody almost the entire matter of these papers, with the illustrations, in the articles which we shall give to our readers. In the chapter given by Beale on this subject, there are a number of valuable suggestions and additions by Mr. Swift, the well-known microscope maker.

Mr. Ross, who contributed the famous article on the microscpe to the *Penny Cyclopædia,* also gave some instructions for preparing polishing powders*, for producing flat surfaces in glass, and for setting lenses. "Ree's Cyclopædia" also contains some practical matter scattered through different articles. Outside these works we know of nothing that is available to the young student.

We have thought it well to point out these sources of information so that our readers may have an idea of how little there is to be found on the subject. Ordinary books on chemical and physical manipulation (such as Faraday's and Williams' works on "Chemical Manipulation," and Frick's "Physical Technics") do not touch upon the subject of glass grinding at all.

One question which will probably occur to the minds of our readers we may as well answer here. It is this: How much optical knowledge must the student have in order to succeed?

Of course the more the better, but at the same time it must be acknowledged that but a very slight acquaintance with the laws of optics is necessary to enable one to make even a tolerably good objective, and to use it with good effect. The reader who will master the ordinary chapters on optics in our school philosophies will be able to follow out the practical parts of these articles to good advantage. Particularly should he study the course of light through ordinary lenses, and the way in which these lenses form images greater or less than the object which makes the image. He should become familiar with the forms and names of the different kinds of lenses, as plano-convex, double convex, meniscus, etc., and he should inform himself in regard to the elementary facts and laws which govern the decomposition of light by the prism. This much is easily learned, and may be found in any text-book on Natural Philosophy. Those who desire a popular and yet thoroughly accurate book on the subject, would do well to study that part of Deschanel's Philosophy that is devoted to

*The directions given by Mr. Andrew Ross, Lord Ross, Holtzapffel, and others, for preparing polishing powders, are published in full in the "Workshop Companion."

optics. Having gone thus far the reader will be able to guide himself, and the further he goes in this direction the better work will he be able to turn out.

To be able to make the lenses for a microscope or telescope we must have: First, a knowledge of the proper forms of the pieces of glass that are needed, and also of the qualities of the kinds of glass best suited to the different parts; and, secondly, the mechanical ability to work these different pieces of glass into proper shape. The second requisite is that which in practice makes itself felt first, and we shall, therefore, turn our attention at once to the materials and tools required.

GLASS.

Glass is the material out of which all lenses for purely optical purposes are now made. Chemists enumerate nine different kinds of glass, but of these two only, flint glass and crown glass, are generally employed by opticians. Speaking of the glass used in making the best modern objectives, Mr. Wenham gives us the following information, much of which will at present be beyond the understanding of the majority of our readers, but, as we desire to make these articles complete and furnish information which will be valuable to advanced students, we give it unabridged. He says:

"Under this head I can offer but very little information, for, in common with all other workers in this direction, I have merely made use of such various samples of glass as I have been able to procure. The whole secret of the ingredients used, their proportions and chemical constitution, is in the hands of the makers; and though the two or three of them who have paid attention to the manufacture have doubtless well studied the particular application of both the flint and the crown for the construction of microscopic lenses, yet the best that we can procure falls far short of the requirements of the case for the very highest powers.

"It is usual to denote the quality of flint glass by its density, but this in reality forms no accurate criterion of its dispersive power. Formerly, under this impression, I procured a quantity of dense flint, made by Chance, of Birmingham—very hard, white, and free from ability to tarnish, and to all appearances as good a quality of glass as I had seen. Its density was 3·867, but on trial I found it unfit for the construction of the highest powers, as its dispersive power was lower than the Swiss 3·686, or even the 3·630 that I had employed previously while its refraction was much greater. Some ingredient had been added which increased the refraction, and probably lessened the dispersion; and, of course, in a correcting concave, the latter quality alone is needed, and the lower the refraction the better.

"The crown and flint employed in the one-eighth described at the commencement of this essay,* of the respective densities of 2·437 and 3·686, had a relative dispersive power of 11 to 25; this having been very accurately determined by two prisms, whose angles were in this proportion, and which, when superposed, were perfectly achromatic. Faraday made some dense flint having a specific gravity as high as 6·4, but we have no information relating to its refractive and dispersive power.

"We are thus somewhat ignorant of the material elements of construction employed in the microscope object-glass; and it would be very desirable that a series of experiments should be made, with various combinations of all the known materials that can be used in glass-making, and the resulting compounds worked into equilateral prisms, and their refractive and dispersive powers tabulated, with the component ingredients. A few years back this investigation would have been a very troublesome and expensive one, by reason of the interference of the Excise laws, and the necessity of employing a regular glass furnace, to operate on large quantities at once, in order to lessen the effects of impurities. But now, by means of the recently invented gas furnaces, the greatest possible heat may be commanded, under perfect control, and thus enable the operator to combine materials in very small

*In a subsequent number we shall publish Mr. Wenham's directions, illustrated with cuts, for making this objective.

quantities without the intrusion of impurities from the fuel and furnace-lining, or crucible, which may be of platinum. The results of the investigation would unquestionably be valuable, and we might possibly be able to discover compounds which would neutralize the secondary spectrum. The late Thomas Cooke has repeatedly stated that if, while viewing a difficult double star through a telescope, some one was to sweep away the secondary spectrum, he would scarcely be able to discover any improvement, either in light or definition. But I am of opinion that the case is different with a microscope object-glass, wherein, with the highest powers, every trifling error is so enormously magnified, and in resolving the most difficult tests the effects of irrationality are at times very apparent."

Transferring Prints and Leaf-Forms to Wood.

TO transfer pictures to sycamore or white pine, you must first plane your wood perfectly smooth, and give a few coats of French polish; then take your picture, and damp it with a sponge soaked in spirits of wine; place the picture on the wood, and then place a piece of thickish cloth over the picture; then get a warm iron and rub gently over the cloth, being careful not to shift the picture. You must keep rubbing the iron backwards and forwards for ten or fifteen minutes, then take off your cloth and leave it for some hours. Then you must get some cold water and damp your finger in it and rub the paper. Great care must be taken in this, or you will disturb the impression. Keep damping your finger as you go on. When you have got it all off you can polish over. Any kind of picture will do with the exception of glazed ones. Ink pictures take off best. There is another method by which the effect of white leaves prettily grouped on a dark, softly graduated ground is produced. The leaf or pattern is fastened temporarily to the wood, which must, of course, be nice and smooth, fit for varnishing. Then take a brush of stiffish bristles filled with some pigment. Bend back the bristles towards you, and away from your pattern, then let go suddenly. Some of the pigment will then be precipitated on the wood where not covered by the pattern. You proceed in this way till your judgment tells you the pattern is well defined, taking care to vignette or allow the shadow thus produced to fade away towards the edges. You may advantageously practice with a blacking brush, using blacking thinned down with gum water for the pigment on a sheet of paper, using a fern leaf or two for patterns.

A Cipher.

THE word cipher has various meanings. It is usually applied to the figure 0, which is equivalent to zero or nothing. It also means a combination or intertexture of letters, as the initials of a name, the several letters being intertwined so as to form one figure. Such figures, or *monograms* as they are now generally called, were very generally used by painters and

MONOGRAM CONTAINING THE ENTIRE ALPHABET.

engravers, each of whom was known by his cipher.

The cipher or monogram in the accompanying engraving contains all the letters

of the alphabet, and will prove a study for some of our young readers.

The word *cipher* also means secret writing—the proper name for which, however, is *cryptogram*. During the war, dispatches were often sent in cipher, and politicians and lovers sometimes use cipher dispatches when they wish to keep their messages secret. The following example of a cipher will interest our readers. It was composed by Prof. Whewell at the request of a lady:

You 0 a 0, but I 0 thee,
O 0 no 0, but O 0 me,
O let then thy 0 my 0 be,
And give 0 0 I 0 thee.

Which being figured out means:

You sigh for a cipher, but I sigh for thee,
O, sigh for no cipher, but Oh, sigh for me,
O let then thy sigh for my cipher be,
And give sigh for sigh—for I sigh for thee.

Scroll-Sawing.—VI.

BY F. T. HODGSON.

THERE is no branch of scroll-sawing that will give pleasanter results or afford more amusement than the cutting of silhouettes. Sheets of designs for this purpose can be obtained at almost any book store for a very small sum. Many excellent designs can be found in illustrated papers and books for children, wall papers, and illustrated labels. A silhouette is simply an outline of some figure. and when cut with a fret saw, as a rule, has no inside cutting; Fig. 26 will give you a good idea of what constitutes a silhouette. They should form material not more than one-sixteenth thick. Hard rubber, ebony, black walnut, and rosewood on the one hand, and white holly, rock maple, and basswood on the other, are used for this work. Silhouettes may be employed for a thousand decorative purposes; and if you possess a good treadle machine you can find, if you desire, employment enough in this direction in making an infinite number of ornaments for your own and your friends' homes. Cornices for windows, doors and rooms can be made by this process, that will be highly ornamental if neatly and properly done, and taste and judgment employed in the selection of patterns. To form a cornice, say for a bedroom ceiling, paste a strip of dark colored paper all round the room close into the angle, and on the upright wall. The strip of paper should not be less than half an inch wide for every foot in height of the room; thus, if a room is ten feet high, the strip should not be less than five inches in width. It will stand to be wider, but will not admit of being narrower than as above. This strip forms a background for the whole work, and it may have a different colored

Fig. 26.

strip, or a gold bead, half an inch wide, running on its lower edge all round the room, or may be cut serated or wavy on the edge, as the taste of the workman may suggest. When this is done, cut your silhouettes according to pattern chosen, of maple or white holly, four or five at a time; when the number cut is sufficient to go round the room, they should be glued on to the strip of paper, being careful not to daub the latter all over with surplus glue. When this is finished satisfactorily, if desirable, a smaller pattern of walnut or ebony may be cut and glued on the white holly or maple, and this again

touched with gold leaf in the centre, or a small flower in colors might be painted on each piece. Making a cornice of this kind is a very simple matter, but when completed is sure to give pleasure to all who see it. The workman of tact will find suggestions crowding on him thick and fast as he proceeds with his work, and more elaborate cornices will be easy of design after the first one is completed.

Borders for panels, corner ornaments, and centre-pieces for door panels, pictures, cartoons and animals, can be cut out of veneers with very little practice. If you wish to saw out a perfect likeness of any one, in profile, stretch a piece of strong white paper over a frame prepared for the purpose, and about two feet square; let the subject sit between a strong light and the paper, and in such a position that the shadow in profile will fall directly on the latter, which must be held securely in its place. Now trace the outlines of the shadow on the paper with a soft lead pencil, on the dark side of the frame. If neatly done you will have an exact likeness in profile of your friend, which can be reduced, preserving the features correctly, by using a good pantograph. With a little practice in this line you will be astonished at the excellence of your own work. If you wish to make the likenesses distorted, and still have them preserve the general character of outline, you can do so by holding the paper at different angles, and by a little adjustment of the frame you will soon discover what position will insure the funniest results. Once having obtained a good likeness, you should keep it for a pattern, and you will not be long in finding use for all the duplicates you may make. If you are the happy possessor of a printing press you can find plenty of employment for your saw in cutting letters of every description for use in your press. Cut the letters from hard veneers and glue them on blocks of maple or beech, taking care that the type when completed are the exact thickness of other type. I have known a country printing office where all the display type for large bills and posters were made this way, and satisfaction was given every time they were used, and the saving in expense was considerable. Borders, corner ornaments, figures, and many other things for printer's use can be made with a good saw in skilful hands.

Although I have made no use of the word or words "overlaying," I have treated somewhat on the subject. It simply consists in cutting out fine ornaments and fastening them on a dead surface of some kind, such as panels, drawer fronts, box lids, album covers, etc., etc. Ordinary flat picture frames can be overlaid with vines or fine tracery. Very nice photograph frames can be made by taking a thin pine board and sawing an oval out of the centre, and covering the pine with velvet. Fasten the overlaying on the velvet. Designs for overlaying, such as corner ornaments, vines, flowers, heads, borders, monograms, fancy letters, and other pretty devices can be picked up in books, prints, and illustrated papers; or they can be bought from the regular dealers in scroll-sawing materials.

Looking Into Dark Places.

IT is often necessary to examine the bottom of a tube or hole. Wells and gun-barrels afford familiar examples. Nothing is easier provided we illuminate the cavity by means of a good light thrown down by a mirror. For wells, cisterns and ponds a good common hand-mirror will answer, but for narrow tubes, like gun-barrels, a little management is required. The mirror must be held so as to reflect a strong light (sunlight is best, but any good lamp will do) down the barrel, and at the same time it must be so placed that the eye can see past its edge and look down the tube. This can be done, but a great improvement is to scratch a small oval hole in the silvering, so as to leave the mirror transparent at this point. It then becomes easy to look down the barrel through this hole, while the silvered part of the mirror covers the whole of the tube and throws a flood of light down it. In this way rust spots and imperfections can be detected at the bottom of the smallest bores.

For wells and ponds no such refinement is necessary. When the sun is shining brightly, hold a mirror so that the re-

flected rays of light will fall into the water. A bright spot will be seen at the bottom, so light as to show the smallest object plainly. By this means we have examined the bottoms of wells fifty feet deep, when half full or more of water. The smallest straw or other objects can be perfectly seen from the surface. In the same way one can examine the bottom of the ponds and rivers, if the waters be somewhat clear and not agitated by winds or rapid motion. If a well or cistern be under cover, or shaded by a building so that the sunlight will not fall near the opening, it is only necessary to employ two mirrors, using one to reflect the light to the opening, and another to reflect it down into the water. Bright sunlight may be thrown fifty or a hundred yards to the precise spot desirable, and then downward. We have used the mirror with success to reflect light around the house to a shaded well, and also to carry it from a south window through two rooms, and then into a cistern under the north side of the house. Half a dozen reflections of light may be made, though each mirror diminishes the brilliancy of the light. Let any one not familiar with the method, try it, and he will not only find it useful, but a very pleasant experiment. It will, perhaps, reveal a mass of sediment at the bottom of a well that has been little thought of, but which may have been a frighlful source of disease by its decay in the water.

Drawing Lessons.—V.

BY JOHN CLARK CENTER.

WE will now turn our attention to exercises that will require a different method of treatment, and develop a quick and free use of the hand and pencil.

The examples of curved lines in Fig. 1 must be practiced, and the pupil must not rest satisfied until he is able with a single sweep to draw them correctly. He should attempt to draw these curves in all manner of positions, beginning at the top, then at the bottom, and making the curve upwards, and so on, until the utmost facility is attained in drawing them, however placed. The curved line, known as the

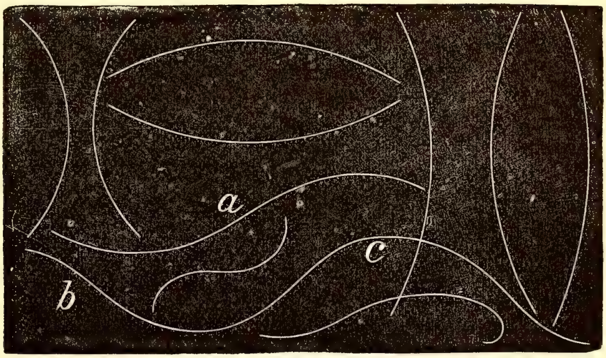

Fig. 1.

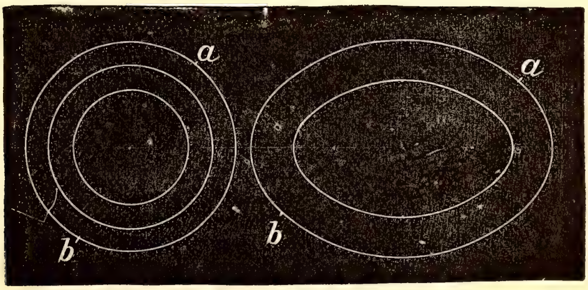

Fig. 2.

"line of beauty," *a b c*, must next be mastered; it is of the utmost importance to be able to do this easily and correctly.

Circles, and ellipses or ovals, must also be drawn independent of mechanical methods. In Fig. 2 the circle, beginning at *a*, sweeps round by the right to *b*, then from *b* towards the left and up to *a*, where first begun. The pupil may also try to draw it the reverse way. Circles within circles may be thus drawn, and ovals within ovals in the same manner. In sketching ancient or modern architectural edifices, the combination of straight and curved lines will be called for to describe the various orders of architecture, which can be either studied from nature or in works treating on that art.

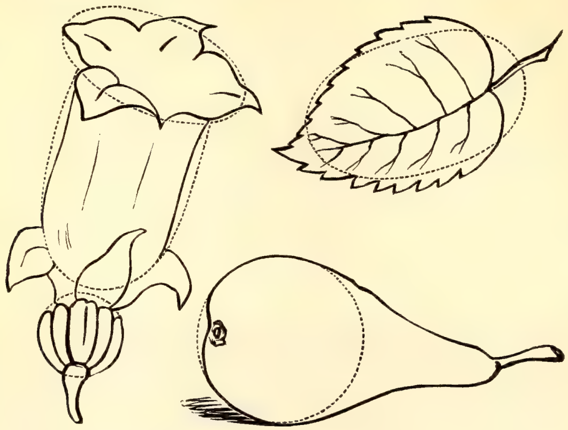

Fig. 3.

In Fig. 3, for the leaf a correct ellipse is first drawn. Thereafter the top *(a)* and the end *(b)*, rubbing out the parts not required, the fibres and serated edges are added and the leaf is finished.

The pear exemplifies the use of the arch, and the analytical sketch of the flower will illustrate how all varities of similar objects may be treated.

The pupil, in drawing figures and objects from nature, should provide himself with cartridge paper; this material has a rough surface, which takes the pencil easily and will bear rubbing out well. Also a few black lead pencils; some rather hard to make the outlines, and others soft for shading. Having selected a subject for study, a careful outline sketch must first be made. An old dilapidated building, stile, or pump, are favorite examples for practice, with the trunk and foliage of a tree.

Endeavor to produce the proper degree of shade at one operation, only having to retouch and strengthen by cross-strokes or greater depth, to produce effect or relief. In all well-executed engravings will be found examples of treatment of light and shade, and the pupil can easily and cheaply procure some of those drawing copies, which will facilitate progress in any department of drawing in which he may aspire to perfect himself.

We can only hope, in this brief but suggestive treatment on art, to inspire a taste for the useful and beautiful; perfection in any department can only be acquired by years of steady application and study.

Why Franklin Used Simple Language.

TRADITION has it that years ago, when Benjamin Franklin was a lad, he began to study philosophy, and soon became fond of applying technical terms to common objects. One evening, when he mentioned to his father that he had swallowed some acephalous mollusks, the old man was much alarmed, and suddenly seizing him called loudly for help. Mrs.

Franklin came with warm water, and the hired man rushed in with the garden pump. They forced half a gallon down his throat, then held him by the heels over the edge of the porch and shook him, while the old man said: "If we don't get them things out of Benny he will be pizened, sure." When they were out, and Benjamin explained that the articles alluded to were oysters, his father fondled him for an hour with a trunk strap for scaring the family. Tradition adds that ever afterward Franklin's language was marvelously simple and explicit.

Shadow Plays.

As a means of furnishing amusement to a small party of children (whether of large or small growth is a matter of no consequence), the old fashioned "shadow play," as it is called, can scarcely be excelled. It is so easily prepared, and requires so little experience or skill to work it, that we have often wondered that it is not more generally known.

Fig. 1.

The simplest form of shadow play, or shadow illusion, as it is sometimes called, is that known as "*The Witches Dance*," or "The Dance of Death," according as the figure which throws the shadow is that of an old witch with her broomstick, or a skeleton, and the play consists in throwing a number of these shadows upon a transparent screen, and causing them to move about in various grotesque ways. The shadows, however, are generally produced by one figure, which is cut out of pasteboard, and hung a short distance in front of the screen, as shown in Fig. 1. If our young readers will cut such a figure (of small size) out of card-board, and hang it before a wall, and then bring a candle or lamp behind it, of course a shadow will appear on the wall, and the closer the candle is to the figure the larger will be the shadow. If the candle be held at one side, the shadow will be made long and narrow; if above or below, the shadow will be short and dumpy. If the candle be moved with a quick jerk, the figure will appear to jump, and if the jerk be very quick and from a state of rest to a state of rest, the effect is more like magic than anything else. If the candle be moved slowly the figure moves slowly. If, however, there are more candles than one, the shadows will be multiplied—a shadow for each candle—and as some candles may be near the figure, and some at a distance, the shadows will be of different sizes and shapes. A little practice in the shape of rehearsals will soon give an insight into

the wonderful variety of effects that may be produced by the varying position of the candles.

The apparatus required is very simple and easily procured anywhere. First, we need a figure. This may be cut out of pasteboard, and the details should be worked out with considerable minuteness and accuracy if we would secure good results. The figure should be suspended behind the screen by several very fine silk threads, the shadows of which will not be seen.

The screen may be simply a sheet suspended between the doors of a double room, or in a hallway. Where this is inconvenient a corner of a large room might be screened off. The sheet should be thin, and to render it more transparent it should be sponged or sprinkled with water.

The lights are simply good paraffine candles. These are safer and more cleanly than hand-lamps, but the latter may be used if necessary. When candles are used, a paper cone should be fastened around them, about one or two inches from the top, so as to prevent the spilling of grease. If very strong lights are desired, four candles may be fixed closely together in a frame. They give darker shadows, but the shadows are not as sharply defined, as we cannot get the candles so close together that each one will not throw a separate shadow, which will overlap its neighbor, and produce a little indistinctness on the edges.

Our engravings show the manner of carrying out what we have described. Fig. 1 shows the operators behind the screens, and Fig. 2 the shadows as they appear to the audience.

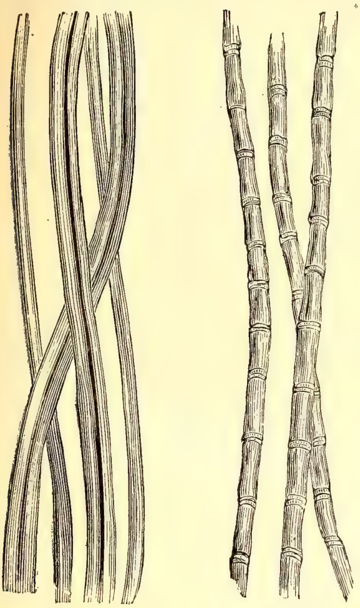
Fig. 2.

—No wonder the country swarms with preachers, physicians, lawyers, and literary mountebanks. There are seven times more nurseries for the propagation of literary pigmies who are taught to feed on the public, than there are to raise and train skillful mechanics, engineers, agriculturists and miners. Five hundred and seventy-nine colleges, universities, law, medical and theological schools, and only eighty-three schools for the higher mechanical and scientific education, including all schools of design, mining and engineering. There are twice as many theological schools as there are of engineering, scientific and mechanical schools, all told. No wonder that many trained preachers in this country go hungry to bed, while thousands of enterprising mechanics and artisans are floundering about in a sea of ignorance in search of higher "scientific attainments."

Notes on My Cabinet—Silk and Flax.

IN a former article I showed my young readers the difference between cotton and wool; I now give figures of flax and silk, which show very clearly the characteristics of these fibres. It will be seen that while silk is a smooth, even fibre, like a wire, or like spun glass, flax is irregular and knotted like a bamboo cane.

In examining dry goods, for the purpose of finding out what they are made of, it is



SILK. FLAX.

well to bear in mind the following facts in regard to the origin of these different fibres. Wool is an animal hair, covered with scales, which give it its *imbricated* appearance. It is round, solid and even, and under the microscope the prominent feature is the scales. Cotton is a vegetable hair which, when growing, formed a tube filled with liquid. When the hair dried the sides of the tube came together so as to form a flat ribbon.

Flax is the tissue of the stem of the plant. Instead of being smooth, like cotton, it is hard and solid, and as each fibre has been torn apart from its fellows, it is rough when contrasted with cotton or silk. Many attempts have been made to break the flax up into fibres so fine that they could take the place of cotton. Often and often we have been shown "flax-cotton," as it was called, which the inventors thought could not be distinguished from real cotton. Under the microscope the difference was at once visible, and when worked in the ordinary cotton machinery it showed its character very plainly.

Silk is a fine fibre spun by the silk worm as a covering (cocoon) to protect itself while in a dormant state. The silk fibre is really a solidified liquid. The worm draws the viscid, tough liquid out of its spinnerets, and the fine thread thus produced hardens when it comes in contact with the air. Silk, therefore, has no *structure*, as it is called—that is to say, it is not composed of cells like flax or wool, but is the same throughout just like wire or spun glass. The *gut* used by fishermen is the same thing, but thicker fibres. Instead of being spun by the worm, however, it is spun by men who kill the worm, expose the bag of liquid, and draw it out so as to form a thread of the desired length and thickness. Gut is, therefore, merely a stout thread artificially produced from the same substance that is used by the silk worm to produce silk.

O. W.

A Cheap and Simple Camera for the Microscope.

THE following capital little device is described by Mr. T. B. Jennings, in the *American Journal of Microscopy*, and we republish it from advance sheets of that journal:

Probably there is nothing that will assist the student in microscopy so thoroughly as drawing the object, as he thereby *fixes* the different parts in his mind.

A good camera lucida is too expensive for many persons, while other and more necessary accessories are being purchased.

Having made a good reflector for my own use at *no* expense, and thinking that many of your subscribers might desire to do the same, I give the mode.

Take a flat cork, Fig 1, *a* (mine was from a large-mouthed bottle), cut a hole, *b*, through its centre large enough to fit over the eye-piece after the cap has been

removed. Just below the hole make an incision, *c*, so that it will hold a thin glass cover, *d*, at an angle of 45°. I use a cover ¾ of an inch in diameter.

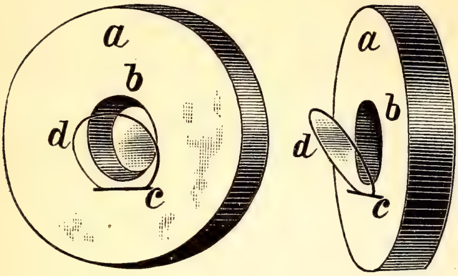


Fig. 1. Fig. 2.
CHEAP CAMERA LUCIDA.

The "reflector" can be easily removed when not in use, and the glass readily taken out to be cleaned. Fig. 2 is a side view.

Editorial Notes.

The Young Scientist for 1880.

IN commencing a new year it may not be out of place to give our readers a few hints in regard to the articles we have in store for them. In addition to the series which have already been commenced, such as Mr. Hodgson's articles on Scroll Sawing, the articles on the Battery, on Home-made Telescopes and Microscopes, Magic, Drawing, etc., we have a series on the Turning Lathe, by Mr. Harrison (author of a well-known work on small tools); another on Home-made Magic Lanterns, one on Amateur Silk Culture, etc. Considerable attention will be given to Amateur Microscopy.

The articles by Mr. Wright, on Astronomy, will be continued during the year, and he has promised us a series of Notes on the Moon. These cannot fail to prove deeply interesting, especially to beginners in astronomy. With the March number we will send out a fine Map of the Moon, twelve inches in diameter, reproduced from Beer & Maedler's "Mappa Selenographica." This will illustrate Prof. Wright's articles, and to those interested in astronomy will be worth more than the price of the YOUNG SCIENTIST for one year.

We ask our readers to do all they can to increase our circulation and help forward the good work. Remember that the YOUNG SCIENTIST is the only journal of the kind in the world. Several very earnest attempts have been made to start journals of a similar character, but they have all, without exception, failed. The YOUNG SCIENTIST is the only one that survives. Story papers have sprung up by the dozen, and they flourish amazingly, and some of those recently started make a great flourish of trumpets about occupying the field we have taken up. It still remains a fact, however, that the YOUNG SCIENTIST is the only journal which is strictly devoted to experimental science and amateur arts.

We do not ask any one to help us without an equivalent, but if you think that the YOUNG SCIENTIST deserves support, send in your own subscription and get up a club amongst your friends.

To Our Subscribers.

WE send this number to all whose names are on our books—whether paid or unpaid. As the subscription to the YOUNG SCIENTIST is too small to allow us to incur the expense of postage and letter-writing for the collection of old accounts, the journal cannot be sent after this date to those who have not renewed their sub-subscriptions.

Designs for Scroll-Sawyers.

MR. HODGSON, whose admirable articles on scroll-sawing are now in course of publication in the YOUNG SCIENTIST, has prepared for us a series of seventeen designs covering a great variety of. subjects suitable for Christmas presents and ordinary articles of household ornament and utility. These designs we have had photo-lithographed and printed on two large sheets. They are full size and embrace over eighty different pieces. Knowing that this set must have a large sale, we have placed the price at 25 cents for the set, or a cent and a half for each design. We know of no designs equal to these which can be had for less than five, ten, or twenty cents each.

To any boy or girl who will send us a new subscriber, (together with their own

subscription) we will send a set of these designs free. The subscriptions may be for 1878, 1879, or 1880. Remember, one of the subscribers must be new. It will not do to send a renewal of the subscriptions of two old subscribers.

BOOK NOTICES.

Some Practical Hints on Wood-Engraving, for the Instruction of Reviewers and the Public. By J. W. Linton. Price $1.25. Boston: Lee & Shepard.

Some time ago Mr. Linton published an article in the *Atlantic Monthly* on "Wood-Engraving," and the present volume is a reply to the criticisms which that article called forth. In his first article, Mr. Linton criticised severely, and we think with justice, certain new departures in wood engraving, which have recently appeared in some of our prominent magazines. As distinguished from the older styles, these new methods are characterized by a certain nebulousness which the authors seem to mistake for softness or something else, but which gives us simply the impression that the photographer who transferred the original drawing to the material on which it is cut, did not take the requisite pains to get his picture sharply in focus. It is, consequently, indistinct, as well as flat and inexpressive. Those who go into extacies over the new style seem to be led astray by the idea that because in some paintings the outlines are indistinct and yet wonderfully suggestive, therefore this quality may be transferred to a wood cut simply by blurring the outlines. No greater mistake can be made. Every painting and every engraving is valuable for two things—what it tells and what it suggests, and the latter is often as valuable as the former. And it often happens too that the most suggestive part of a picture is not that which is most sharply outlined. Indeed, the reverse is more often the case, and yet, as we have already remarked, suggestiveness cannot be imparted by indistinctness alone,

Aside from the mere controversy, the book contains much information that will be of value to all who are interested in the art of wood engraving. As regards the merits of the fight, Mr. Linton certainly has greatly the advantage of his adversaries in accuracy of knowledge and clearness of perception.

The Builder and Wood Worker. A Journal for Architects, Cabinet Makers, Stair Builders, Carpenters, Car Builders, etc. Monthly. $1.50 per year. Chas. D. Lakey, 176 Broadway, New York.

The *American Builder* has now been consolidated with the *Wood Worker*, and under the able editorial management of Mr. Hodgson, whose contributions to the YOUNG SCIENTIST have always been so welcome, the combined journals present a most attractive appearance, as well as a table of contents, which render them worth many times their cost to those who are interested in the subjects of which they treat. The *Wood Worker* had already attained a high degree of success, and the *Builder* is well known as one of the oldest journals in this department of the industrial arts. Every one interested in building and wood working should subscribe for this journal.

Astronomy for Amateurs.

BY BERLIN H. WRIGHT.

February, 1880.

EPHEMERIDES OF THE PLANETS.

(Calculated for the Latitude of New York City.)

	D.	*H.*	*M.*	
Venus rises	10	4	56	morning
" "	29	5	6	"
Mars in Meridian	10	6	21	evening
" "	20	6	1	"
" "	29	5	45	"
Jupiter sets	10	7	34	"
" "	20	7	7	"
" "	29	6	42	"
Saturn "	10	9	36	"
" "	20	9	1	"
" "	29	8	31	"
Uranus in Meridian	10	1	20	morning
" "	29	11	58	evening
Neptune sets	29	10	41	"

NEAR APPROACH OF MOON TO STARS AND PLANETS, ETC.

Day.

1. Moon 4° North of Spica.
5. " 2° " Antares.
7. " 1¾° South of Venus.
7. " 5° North of "Milk Maid's Dipper."
12. " 6¼° " Jupiter.
14. " 8° " Saturn.
14. Mercury superior conjunction with Sun.
17. Moon in Pleiades.
18. " 1½° North of Mars.
18. " 10° " Aldebaran.
19. " 18° " Betelguese.
22. Moon midway between Procyon and Pollux.
23. Mars 90° East of the Sun.
24. Moon near Regulus.
25. Uranus 180° from Sun. (*Brightest.*)
28. Moon 5° North of Spica.

EASY TELESCOPIC OBJECTS.

Uranus may be seen with any ordinary telescope, but it requires an aperture of 4 inches or more to give sufficient light to define a disc, which only subtends an angle of 4″, and the best telescopes only show a dull bluish disc. Place, Feb. 10, R. A. 10h. 38m. 33s. Dec. 9, 9° 27′ 29″ +.

Orion is favorably situated for observation, not having an uncomfortable altitude, and being on the meridian at 8 o'clock in the evening in the early part of February. This is con-

sidered to be the grandest of the constellations, and the observer will be well repaid for careful observation. It has fewer Nebular objects than Ursa Major, but grander, and it contains such a vast number of bright and double stars, and clusters, that it affords a far richer field for the astronomical observer. It contains two stars of the 1st mag., four of the 2nd, and three of the 3d. The great nebula and the trapezium have already been described and figured in the YOUNG SCIENTIST for March, 1879, p. 46.

Betelguese is the most brilliant star, being, when brightest (it is an irregular variable), the "largest star in the northern hemisphere." Lasell says of it: "A rich topaz, in hue and brilliancy differing from anything I have ever seen." It is double; companion 9th mag., 160″ distant. A line from Betelguese through the belt, continued nearly as far again, will reach Rigel, a double, and the brightest star below the belt, and one which will severely test the observer's telescope, if small. The companion is of the 9th mag. and distant 9′.5; its combined closeness and smallness render it difficult, but it has been separated with an aperture as low as 2¾ inches—we have seen it with a 3-inch achromatic—companion, blue.

Very close to the lowermost star in the belt (½° west, and a trifle lower) is a bright white star of the 4th mag. This is a fine multiple star—a double triplet, with two fine stars between the sets, and easily found. Fifteen stars have been counted in this group—eight with a good 3-inch glass. This is a most interesting object, even when very small telescopes are used, and it also forms a good test-object for distinction. Color of companions: bright white, ash-colored, bluish, grape-red, dusky, white, and pale-grey.

We have not yet told the half of the richness of this constellation, but must close.

Jupiter is too near the sun to admit of satisfactory observation of the phenomena of his satellites.

Penn Yan, N. Y.

Finishing and Polishing Brass.

Many who hear the words "brass finisher" may be led to believe that this would apply to those who produce highly-finished work; but it is not so, the brass finishers in reality are not the superior class of workmen supposed, the work most of them do is comprised in gas-fittings, ormolu mounts, etc.; but the high class of brass finishing is a totally different process. We will take several examples: First, say fittings for gas work, all well-enough finished for their several purposes, and quite as well done as the price paid for them will allow. Then we come to the mountings for furniture; these must obviously be produced at a low price, in order to supply the demand for cheap things of this character. We will now pass on to a totally different class of work—for instance, microscopic and philosophical instruments. These are most beautifully finished, and must also be made in a superior manner, before any attempt can be made to finish them; also the beautiful parts that are now made to the turning lathes of the present day. As this particular branch affords scope for the explanation of really good brass finishing, we will take a few parts of the lathe and its various appurtenances. In making an eccentric chuck, a deal of high-class work will be required. We cannot call a piece of work well finished that is simply very bright, but full of scratches. High polish and deep scratch must at all risks be avoided, as the latter are a sign of indifference on the part of the workmen. To begin, or rather before commencing to finish and polish, all marks of the file must be removed, and this is done thus: Having used a superfine Lancashire file to draw the edges and file the surfaces, take a piece of moderately fine emery paper and wrap it tightly round the file, only once round. It is by having so many folds round the file that the work becomes rounded off at the edges, and made to look like second-hand things that have been cleaned up several times. Some workmen use emery sticks; they are made by having several pieces of wood planed up, about ⅜ inch thick and ¾ inch wide, quite flat on the surfaces. This done, they are covered with a solution of thin glue, and the emery powdered on to them, and then allowed to dry hard. Most of the common work is, I will not say finished, but rubbed over with emery cloth. This is all well and good for such purposes, but it will not do for good work. Having folded the paper once round the file, it is worked in a similar manner to the file, and when the file marks disappear, and the paper is well worn, a little oil should be used with it, as this fills up the paper and makes it cut smoother. Having got up the edges and surfaces to this extent, to finish the edges must be the first thing, and the best way to effect this is to have a piece of soft wood, quite flat, and rub on its surface a little oilstone powder, free from grit. Now, the best way to be sure of having it quite clean is to have a piece of old Turkey-stone by you, and as you want to use it break a small piece off and pound it on the corner of a surface, or anything equally hard. You will then be sure that it is quite clean. It is exceedingly annoying to make a deep mark in the work just as it is finished, perhaps a mark that will require

filing out. However, it is better to avoid doing it than to have to eradicate it after it is done.

When the work has been well finished with the stick and oilstone powder, a clean buff, with a little rottenstone and oil, and then dry rottenstone should be used, and, if properly done, a most beautiful, bright, clean, and flat finish is obtained. Having finished the edges thus, to do the surfaces will be the next part. They, also, must have all the marks of the file taken out, and be got quite smooth from the paper. This done, if it is to be curled, which is the best and most ornamental way of finishing such work nowadays, a piece of water-of-ayr stone, used with water, will remove such scratches as may be left from the emery-paper; also, it produces a kind of cloud, previous to using the charcoal, which is the next process. Take a piece of cutting charcoal, which, by the way, there is some difficulty in obtaining, and it can only be got by going to some coal shed which, as a rule, is not of the most inviting; but if a thing is really wanted it must be obtained, even at the risk of having to attend one of these disagreeable habitations; and as I am telling our readers of the means of getting what they require, I may as well tell where the place is. In Crown Court, I think it is, in Newport Market, this material is to be found, and as there are several kinds, it is better to take a piece of brass and try it before purchasing, as some will cut, some will not, and out of fifty pieces perhaps only two or three will be of any use. Now having, we will assume, procured the material, unless it is properly used we may as well be without it. Before trying, file one end flat, and having a small basin of water by your side, dip the charcoal into it, and by curling it round and round in all directions the clouded surface is formed. Now, it must not be thought that by simply doing this that a good result will be obtained, for it is, in reality, a difficult thing to do, and unless well done it looks very inferior, and would be better left alone. When the surface is finished with this process, the next thing to be used is a piece of slate pencil brought to a point. This is also used with water, to make it cut, and is made to produce a series of small circles or rings, which must not be done with any regularity, but indiscriminately in all directions. There is great knack in all these different styles of finishing work, and there are not two men that do this particular branch in the same manner. This done, the next thing will be to lacquer it. This is similar to varnishing wood, the difference being that the metal must be made hot. I do not mean red hot, but after it has been well wiped over and brushed out with whiting, to take all the grease out, it should be put on a piece of red hot iron, and remain there till it is so hot that your finger would be quickly withdrawn if placed upon it. When it is taken off the iron, well wipe it again with a clean, dry rag, because where there is any grease the lacquer will not take, and on those parts it will show a dirty discolored mark in a short time. Always lacquer the edges of your work first. In using the brush a very light hand is necessary, and no more lacquer let in the brush than you can help. Above all things, both lacquer, brush, pot, and work must be free from dirt and dust. By following out these directions the superior finish seen on the best work may be obtained, and after all there is really little difficulty in it; care is one of the most essential points, and without that good work of any kind cannot be done.—*Forge and Lathe.*

Good Joints.

Our young friends who exercise their ingenuity in the construction of useful articles, and especially in making repairs about the homestead should give particular attention to the formation of the joints by which the different parts are united. One of the highest authorities, the late Professor Rankine sums up the principles which should be adhered to in designing joints and fastenings in carpentry, concisely as follows: First, to cut the joints and arrange the fastenings so as to weaken the pieces of timber they connect as little as possible. Second, to place each abutting surface in joint as nearly as possible perpendicular to the pressure which it has to transmit. Third, to proportion the area of each surface to the pressure which it has to bear, so that the timber may be safe against injury under the heaviest load that occurs in practice; and to form and fit every pair of such surfaces accurately, in order to distribute the stress uniformly. Four, to proportion the fastenings so that they may be of equal strength with the pieces which they connect. Five, to place the fastenings in each piece of timber so that there shall be sufficient resistance to the giving way of the joint by the fastenings shearing or crushing their way through the timber.

Practical Hints.

Liquid India Ink.—When India ink is kept in a liquid state it soon becomes worthless, from the fact that the gelatine which it contains decomposes. A little glycerine added acts as a preservative, and causes the ink to flow well. Too much glycerine will prevent the ink from drying, and in this case it is, of course, easily blotched or smeared.

Ink for Copying Pads.—An ink which will yield a hundred or more copies from a gelatin pad may be made by dissolving rosaniline in a cold saturated solution of oxalic acid. It must be allowed to dry spontaneously.

To Polish Steel.—Mix half a pound of fine flour of emery powder with the same quantity of soft soap, and add a small piece of soda. Simmer this over a slow fire for two hours, to extract all the moisture. Rub on with flannel, and finish with plenty of dry whiting.

Fastening Knives in Handles.—A writer in the *English Mechanic* tells us that knives with tangs should be put into a handle with powdered alum, the tang made hot as for resin. Let the handle be wood, iron, ivory, bone, or horn, it will be immovably fixed unless the handle is split, and far more cleanly than resin.

Silver Solder.—Writing to the *English Mechanic,* T. Fletcher condemns the addition of brass to this alloy, and says: "The only satisfactory silver solder I have ever used is 11 parts fine silver and 13 parts copper. If brass is used, the solder burns with a blow pipe flame, and runs badly, making very poor and unsatisfactory work. The alloy given above is as tough as charcoal iron, and is always to be trusted. It never burns, and is as fluid as water when melted.

NOTES AND QUERIES.

Queries.

42. In a journal recently started, and which makes great pretensions to scientific accuracy, the *American* inch is given as 39.381 metre. I always supposed that the American inch was the same as the English inch. How is it? METER.

43. I bought a bottle of "silvering fluid" which, when applied to brass stair rods, gives them a very bright, silvery appearance, but after a time they become dull. What can I do to keep them bright? BRASS.

44. I have a fine oil painting which has been varnished and spoilt. How can I remove the varnish without spoiling the painting? AMATEUR.

Answers.

45. METER (42). The British and the American inch are the same, and according to the latest determinations the ratio of the inch to the metre is: Metre=39.37043 inches. Some years ago a statement was made that the American foot was not the same as the English foot, and this error has crept into several scientific books. It has been frequently contradicted, but occasionally it appears again. Another origin for this singular error is the fact that some years ago Congress passed an act legalizing the metre, and in that act it was stated that the metre should be taken as 39.38 inches. It is very evident, however, that this act, so far as it went, legalized an American *metre,* not an American inch. At the same time we believe that the acknowledged metric standard is a copy of the French metre, and this being the case, we have an anomalous condition of things, there being actually two standards in this country.

45. BRASS (43). Your "silvering fluid" is probably a solution of mercury in nitric acid. It does not leave a coating of silver, but of mercury, and this will tarnish in spite of all you can do. If you use a silvering fluid containing pure silver, and then varnish the articles with a very pale varnish, they will remain bright a long time.

EXCHANGES.

Thos. D. Adams, Franklin, Pa., will exchange a $25 lawn mower, $60 coffee roaster, type, cards and books, $60; poultry journals, $10; 2 cocker spaniels, $30; 1 pair do., $80, and 1 pair $60; for key check outfit, improved model press, or offers.

To exchange, 270 foreign stamps, many new and all different, and a boy's printing press, size, inside chase, 3x4¾ inches, worth $9, for books, microscope, or offers. Henry J. Bott, La Fargeville, Jefferson Co., N. Y.

Wanted, a printing press and type; state what is wanted in exchange; "Official" preferred. A. Campbell. Derrick City, McKean Co., Pa.

Dumb bells of all sizes, to exchange for most any thing; send for circular containing weights of them to J. P. Donohue, Box 7, Davenport, Iowa.

A Lozo-pendulum board (lined with genuine billiard cloth), consisting of ring toss, bagatelle, pockets, and ten pin, to exchange for parlor magic, aboriginal relics, or offers. T. C. Gard, Frankfort, Indiana.

Wanted, scientific books and papers, microscope, drawing instruments, telephone, stamps and coins, in exchange for scroll saw, type, cards, revolver, shot gun, magazines, scientific books, or almost anything. W. L. Goodsell, Bath, N. Y.

A pair of New York Club skates, worth $3.50, also coins, minerals and postage stamps, for books or offers; correspondence invited. E. F. Greene, P. O. Box 889, Bath, Steuben Co., N. Y.

A nice marine oil painting, ready framed, worth $5.00; state what is offered in exchange. C. Hammond, Artist, P. O. Box 47, Chatham, Barnstable Co., Mass.

Photographic camera, one portrait and one landscape tube, with chemicals complete, in exchange for medical books. J. Frederick Herbert, 1,324 Poplar St., Philadelphia, Penn.

What offers for 1 Household Microscope, one 8 shot breech-loading carbine, 1 new 7 shot pistol and cartridges, 1 small gold watch, 1 small gold chain, 1 violin and case, one new darning machine. Lock Box 147, Tarboro, Edgecombe Co., N. C.

Back Nos. "Penman's Art Journal" for 1879; Gaskell's Compendium, $1; Coe & Shells' Pen and Ink Drawing, 25c.; Pettengill's Fortune Teller, 40c.; Hand-Book of Business, 25c.; in exchange for microscope, printing press, or offers. M. B. Moore, Morgan Station, Ky.

Trump's and Russel's scroll patterns, worth $10; for large lenses preferred. H. J. Peters, Rogersville, Ohio.

Lessons in Standard Phonography given in exchange for a printing press, lathe, scroll saw, scientific books, hammock, or offers. Phonographer, Box 331, Topeka, Kans.

Wanted, chemical apparatus, in exchange for "Phrenological Journal," $2, and the last six numbers of "American Agriculturist," 75 cents, of 1879. T. P. Potts, Canonsburg, Pa.

Land and fresh water shells, birds eggs, minerals, fossils (correctly named) or books, Gray's "How Plants Grow," Pope's "Linear Perspective Drawing," in exchange for a Multum in Parvo Collecting Box (for eggs). H. Russell, Grassy Cove, Cumberland Co., Tenn.

To exchange cocoons of the Atticus Cecropia for those of other rare moths, coins, stamps, trilobites, etc. Harry L. Shively, 680 N. Delaware St., Indianapolis, Ind.

To exchange for offers, good second-hand set of brass band instruments: 2 E-flat cornets, 2 B-flat cornets, 3 E-flat altos, 2 B-flat tenors, 1 B-flat bass, 1 E-flat tuba. David P. Thomas, Bellmore, Ind.

To exchange, a book, "Linear Perspective," perfectly new, also several other books; state offers. S. B. Wilson, Lenoir, Caldwell Co., N. C.

For exchange, magic lantern, 4 in. condenser, 28 slides, with gas bags and burner, also lamp; for printing press, gun, or anything. E. F. Youngs, Penn Yann, N. Y.

THE Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, FEBRUARY, 1880. No. 2.

Scroll-Sawing.—VII.

BY F. T. HODGSON.

THE young sawyer will find no difficulty in obtaining designs or full-sized patterns for nearly everything that can be made with a fret-saw, at a very trifling cost. There may be cases, however, where designs cannot be procured for particular purposes. When this occurs, the workman will have to exercise his own ingenuity in devising some pattern to suit the emergency. In designing, it is always better to first make a drawing on coarse paper, in lead pencil, of half the pattern, then fold the paper double, and cut through both thicknesses with a knife or scissors, following the pencil lines closely. When finished cutting the paper, unfold, and you will see if the design meets with your expectations; if it does not, cut the one-half to suit, or paste on pieces of paper and cut again wherever necessary, and re-cut. By adopting this method you will soon be able to make handsome designs for any purpose.

The simplest way of applying patterns to the work is to paste the design right on the wood to be sawed, but care should be taken to put the paste on the parts of the pattern that will fall out after cutting; in this way you do not disfigure the part you wish to use. Where the work is to be French polished, it is better to do the polishing before the sawing is done, as a good piece of polishing can not be done afterwards. Oiling or varnishing may be done after the work is cut and put together, but in most cases it is as well to do the oiling or varnishing before the saw touches it.

It requires some little judgment in the selection of woods adapted to the different purposes for which they may be employed. If the work is fine, and full of delicate stems or vinery, avoid knots and select straight-grained, tough wood, and, before sawing, see that it is smooth and ready to receive oil, varnish, etc., as it is difficult to

smooth after being sawed. Most of the woods can be bought ready for the saw; if they are not smooth enough give them a good sandpapering with the finest grade of sandpaper. All kinds of wood will warp or curl more or less if the conditions are favorable, but when this happens the warp or curl can be taken out by damping the floor or a board of sufficient size, and laying the hollow side of the warped stuff on it, and in a short time the warp will disappear. Another method is to dampen the hollow side with steam, then hold the opposite side to the fire until straight. The best woods for the beginner to use are pine, Spanish and red cedar, butternut, poplar, white-wood, bass-wood, and black walnut. The advanced amateur can use to advantage, white holly, mahogany, amaranth, ebony, tulip, rosewood, maple, cocobola, and satin wood. Besides the woods mentioned above, there are many other substances employed in fret-sawing, such as hard rubber, tortoise-shell, ivory, pearl, brass, silver, and gold. The prices of the woods mentioned above, in New York, range as follows per square foot, when one-quarter of an inch in thickness: Pine, 5cts.; white-wood, 5cts.; Spanish cedar, 12cts.; bass-wood, 6cts.; poplar, 5cts.; black walnut, 8cts.; white holly, 16cts; mahogany, 14cts.; amaranth, 25cts.; ebony, 50cts.; tulip, 40cts.; rosewood, 20cts.; maple, 14cts.; cocobola, 25cts.; satin wood, 35cts.

There are also other woods than these that are made use of by the fret-sawyer, but they are scarce and costly, and I think the above-named will furnish a sufficient variety to fill the wants of most amateurs.

Home-Made Telescopes and Microscopes.—II.

FLINT and crown glass for optical purposes are articles of commerce, and are sold by the dealers in optical goods in discs of all sizes and thicknesses. Ordinary sizes are sold by the pound, and as there is a tolerable uniformity in the qualities of the two kinds, as made by any one house, the young optician may safely make his curves to conform to those published, satisfied that he will get very nearly the desired results. It may be interesting to our readers to know that the optical glass of most of the great houses of Europe may be had in New York. Messrs. Chance & Co. have an agency in Duane St., and Mr. Emmerich, of Maiden Lane, keeps on hand a stock of French and German glass. In their first trials, however, our readers will probably use such kinds of glass as they can find, for although it does not require a long apprenticeship to enable the young workman to turn out fair lenses, he must not expect to be able to do it without *some* pratice. Therefore, it will be well to begin on simple magnifiers of medium size and power, and gradually pass to more complicated arrangements requiring greater skill and experience. The making of such lenses is by no means a waste of time, for besides the skill which is obtained, the lenses themselves are always useful for magnifiers, and when mounted in simple handles, as hereafter described, they are useful for dissecting microscopes, and make nice presents to such of our friends as have a taste for botany, entomology, etc.

Such magnifiers may be very well made out of such pieces of common glass as are procurable almost anywhere. It is well, therefore, for the young optician to inform himself in regard to the different kinds of glass in ordinary use.

All glass used for optical purposes must be free from striæ and air bubbles. It is very evident that an air bubble would unfit a piece of glass for making a lens or a prism, and a streak of lighter or heavier glass running through a piece is equally bad, as it produces the same effect that is seen when we look through the heated air rising from a hot stove—objects seen through it are distorted. Glass which is free from striæ or streaks is said to be *homogeneous*, and it is this quality which it is so very difficult to secure in large masses, and which consequently limits the size of the object glasses of telescopes.

In examining a piece of glass for striæ we must be careful not to condemn it on account of wavy irregularities on the surface. These are all removed in working the glass, and do no harm.

The streaks and bubbles which are

always found in bottle glass and common window glass, render them useless for optical purposes. We must, therefore, have recourse to plate glass, which is a kind of crown glass, and flint glass. Pieces of plate glass may be found everywhere, and often of excellent quality, and with very well polished surfaces. Pieces of *old* plate glass are generally so scratched that the surfaces are useless until re-ground and polished, but if a good piece of new glass plate can be had, very excellent plano-convex magnifiers may be made out of it by grinding and polishing the convex side of the lens. For all ordinary lenses good plate glass is the best material, excepting, of course, the regular optical glass. It should be chosen of as light a color as possible, and any pieces in which streaks can be detected should be at once rejected. Sir David Brewster recommends, for non-achromatic lenses, glass of a straw color, whose dispersive power is as small as possible. The color of a piece of glass is of course best seen by looking through it edgewise.

Flint glass of fair quality may be found in many articles of every-day use. Tumblers and goblets of the better class are made of flint glass, and we know a very fair achromatic telescope, the objective of which was partly made out of a large flint glass tumbler. Most articles of cut glass are made out of flint, because this material is more easily worked, and it is also more brilliant, owing to its greater refracting power. Of two lenses of precisely the same curvature, one made of flint glass and the other out of crown glass, the flint glass would have the shortest focus and would magnify most.

Very excellent pieces of flint glass, but of small size, are sometimes found in the pendants of chandeliers.

TOOLS REQUIRED.

The tools required for mere glass grinding are few and simple. Large lenses, such as are used for telescopes, may be ground by hand, but small ones are always ground in turning lathes. For this purpose a very simple and cheap tool will answer—even those cheap lathes which are sold for from five to ten dollars. We have known very good lenses ground and polished by means of a lathe which had been worked up out of some old materials and fitted together with chisels and files. But for setting the lenses so as to produce an objective that will be better than a mere triplet, a really good lathe is necessary. A tolerable lathe is also necessary for turning up the brass tools used for grinding and polishing the glass, and as these tools must be very true, time is saved and a better result obtained by the use of a good lathe. Those who possess a well-made lathe will find no difficulty in making all the tools that are necessary—even those small lathes which are best adapted to the making of very minute lenses. Mr. Wenham describes that used by him as follows:

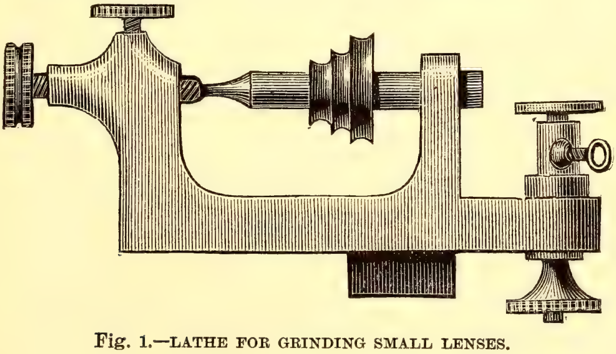

Fig. 1.—LATHE FOR GRINDING SMALL LENSES.

"For the longest radii and lowest powers the ordinary foot-lathe is suitable, but this is not so well adapted for grinding and polishing very minute lenses. A bow lathe, such as is used by watchmakers for heading their screws and other purposes,

is far preferable. This tool is represented half size in Fig. 1, and scarcely needs explanation; it has a hollow screwed mandril and T-rest, and is held in the vice by the tongue at the bottom. The pulley has three speeds, the smallest of which is $\frac{3}{8}$ inch in diameter: it should also have a socket for carrying a fixed magnifier, under which the minutest lenses are turned. The best bow is an old fencing foil ground down so as to be very thin and light. Catgut does not answer well for the string, as it soon gets frayed out over the small pulley. I have found the best packing twine preferable. During work this is kept slightly moist, and rubbed with a piece of soap; in this way a length of it will outlast a day's work, especially if a little more twisted before it is attached to the wire hook at the top of the bow. A surplus stock of string may be wound about the guard, just above the handle, so that it can be drawn out as required."

In regard to the best lathe for mounting lenses, Mr. Swift contributes the following note to Dr. Beale's, work on the microscope:

"The tool best suited for mounting the lenses in their cells is shown in the accompanying engraving (Fig. 2); this can be worked with a drill bow, or can be made to act with the foot, in the way of an ordinary lathe, which is preferable, as it leaves both hands at liberty for manipulating with the slide-rest carrying the cutter. The slide-rest, as will be perceived by the engraving, is of a very simple construction; there are two screws with milled-heads, marked A, (one of which is shown at A, Fig. 2, the other being on the opposite side, and seen in Fig. 3), for the purpose of adjusting the cutter to the diameter of a cell required to receive the lenses. These screws act in opposite directions upon a dove-tail slide, moving at right angles to the mandril of the lathe. B is a bar of metal, about 6 inches long, upon which the cutter is fixed. This bar is planed out Λ shape, and bears upon two supports of similar form. By this means a sliding motion is obtained, in a direct line with the axis of the mandril, upon which the object-cell is screwed. By moving the milled-head screw in Fig. 3, the point of which bears against a stop, any depth of cut required for the combinations can be obtained. The bar B, Fig. 2, when in use, must be held firmly on its fitting, and pushed along until the cut ceases by the point of the milled-head screw coming in contact with the stop before mentioned. Thus the required depth of the cell can easily be obtained. It is best, before proceeding to mount the combinations in their cells, to see that the mount takes a good bearing against the chuck in which it is screwed. If this precaution is not taken it often happens, after the objective is nearly finished, that the lenses first mounted are found to run untrue, owing to the main screw of the mount taking a fresh bearing by the continued screwing and unscrew-

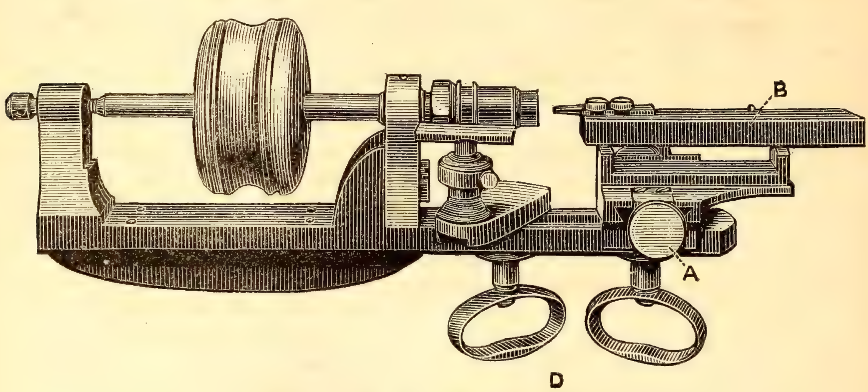

Fig. 2.—LATHE AND SLIDE REST.

ing it off and on the lathe. It will be seen that a T-rest is used in addition to the slide rest. This is handy for making chucks, for turning out the backs of the cells, etc. A rib is seen under the frame

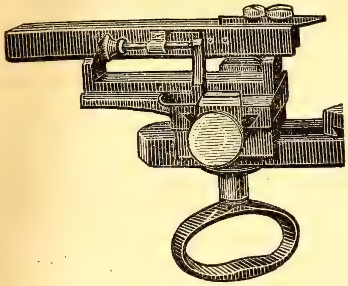

Fig. 3.—SLIDE REST.

The opposite side of the right part of the lathe represented in Fig. 2, and showing the set-screw referred to in the text.

or base of the lathe by which it is held in the vice. If worked by the foot, a wheel treadle can be easily fixed underneath the board to which the vice is bolted."

The Lathe Angle Plate.

BY JOSHUA ROSE, M. E.

THE angle plate is one of the most useful devices employed in holding lathe work, and if properly used will give the most desirable degree of truth or accuracy to the work.

Its uses may be divided into two principal classes; first, to ensure that one part of a piece of work shall be at a true right angle to another part, and, secondly, to ensure that a part of a piece of work shall stand parallel to another part.

An example of the first kind is shown in Fig. 1, in the accompanying illustrations, in which P is a pipe bend requiring to have the faces of its two flanges stand one at a right angle to the other. The angle plate, A, has its two surfaces at a true right angle; hence, when one surface is bolted to the face-plate of the lathe the other will stand at a right angle to the face-plate; hence, if one flange be bolted or clamped to the angle plate, as shown in the engraving, it will stand at a right angle to the face-plate, and the other will be turned parallel to the face-plate, or, in other words, at a right angle to its fellow.

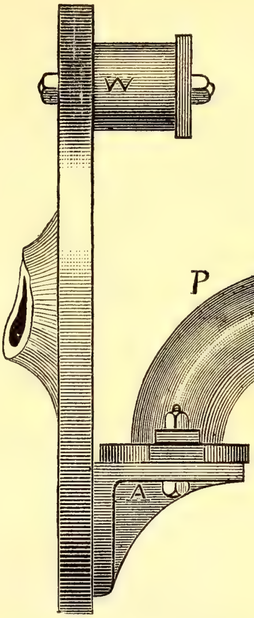

Fig. 1.

It would be a very difficult matter to chuck a pipe bend without using an angle plate. The weight, W, is employed to

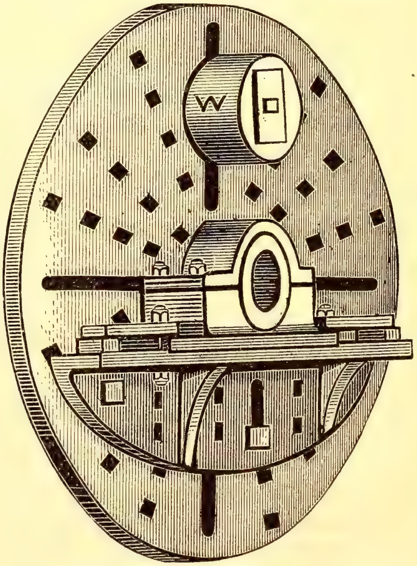

Fig. 2.

counterbalance the weight of the angle plate and the work, because it is found that unless it is counterbalanced in the latter it will be turned oval instead of round. This, however, has no effect upon radial faces, and hence would not affect the pipe bend unless the circumference of the flange required to be turned up.

In Fig. 2 is shown the angle plate employed to ensure parallelism of two surfaces. It is shown holding a pillow-block, which requires to have its hole bored parallel with the bottom surface (shown resting on the angle plate).

The slot and holes shown in the angle plate are to enable it to be moved from or towards the centre of the lathe face-plate to suit the height of the work. The bottom edge of the angle plate is made curved as shown, so as to be able to stand well out on the plate without striking the lathe bed, as it would do if the corners were left square.

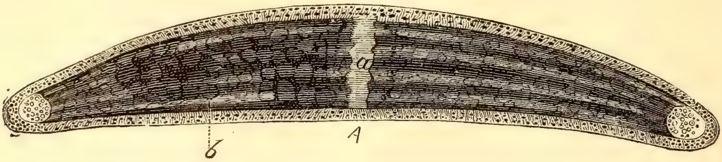
The top surface of the angle plate is provided with numerous holes to receive bolts to clamp the work, which should be held by bolts and plates as shown (and not by bolts passing through the angle plate and through the work), so as to enable setting the work true on the angle plate rather than moving the angle plate endways or on the face-plate.

In setting the angle plate for distance from the lathe centre, a piece of wood should be used, because striking the bare metal with a hammer would soon destroy the truth of the surfaces.

—In keeping living microscopic specimens in small aquaria, the chief points are steady temperature, and neither too much nor too little light. Too much light kills the animals; too little kills the plants.

Pond Hunting.

WHILE there is no doubt that the highest pleasure that can be derived from the microscope, is to be found in its successful application to the practical problems of science, or of daily life, it is also true that the next best thing is the examination of fresh, natural objects, either from the animal or the vegetable kingdom. Compared with living diatoms, desmids, or infusoria, the finest mounted objects are "as water unto wine." The one class may be beautiful, but it is dead and imperfect; the other is living with all its beauty fresh upon it. We might as well compare a fine picture or marble bust with a beautiful living woman in all the power and character of her womanhood, as to compare dead objects with living ones. Therefore, we would most earnestly advise our readers to go pond hunting, if they would get the greatest amount of enjoyment out of their microscopes.



CLOSTERIUM LUNULA.

Natural objects are not difficult to find. They abound in every pool and quiet stream. The difficulty is to find out what they are after we have got them. Knowing and feeling this, we propose to give every month one or two illustrations or pictures of such common objects as are found everywhere. These pictures will be easily recognised, and as we shall give the names and habits of the objects, our young friends will in time form new acquaintances amongst their invisible friends, which will be pleasant if not profitable.

In former numbers of the YOUNG SCIENTIST we have given accounts of the *Volvox*, the *Vorticella*, etc., illustrated with figures. In this number we give a description of one of the most common and beautiful of all the desmids—the *Clos-*

terium lunula. Specimens of this object may be found in almost any quiet pool of clear water. In general, they lie on the surface of the mud at the bottom. This should be very carefully skimmed, so as to disturb it as little as possible, and the collected water should be placed in a glass jar or tumbler, and exposed to the light. When the liquid has settled, so that it is quite clear, the dipping tube may be used to lift a little of the water from a point just over the settlings. The dip should be placed in a shallow watch glass with a flat bottom (a *lunette* glass) and examined with a low or moderate power. It is more than likely that several specimens of Closteria will be seen moving slowly across the field, or lying quietly amongst the confervæ and debris. Once seen, it will never be forgotten.

Editorial Notes.

Postage Stamps.

WE again call the attention of our subscribers to the fact, that while we take postage stamps of small denominations at full value, those of higher denominations are of no use whatever to us. We cannot sell them, except at a very great loss, and the post office will not exchange them for smaller denominations. Therefore, please do not send them.

Good News for Young Astronomers.

AT the suggestion of Prof. Wright we have decided to reproduce the Map of the Moon, after Baer & Maedler, found in "Webb's Celestial Objects," a book which is now out of print. The map will be twelve inches in diameter, and all the principal mountains, seas, etc., will be numbered, so that they may be easily referred to. Prof. Wright will, during the rest of this volume, furnish monthly notes on the *Geography* (if we may use the term) of the Moon, and will give the names and a description of all its most interesting features, as shown on the map.

This is one of the most interesting departments of astronomy, and the only reason why it has not been more generally cultivated is that good maps of the moon have not been readily accessible to amateurs.

As this map forms a somewhat expensive supplement to such a low-priced journal as the YOUNG SCIENTIST, the following are the conditions upon which it will be sent out: To non-subscribers the price will be fifty cents per copy, and it is cheap at this rate; to all whose names are now on our books, and whose subscriptions are paid for 1880 (at whatever rate), it will be sent free. *After* the issue of this number it will be sent only to those who pay the full subscription price for the YOUNG SCIENTIST—50 cents per year. It will not be sent to those who take the YOUNG SCIENTIST at club rates, or where a premium is given to the sender of the club. The map will be sent out with the March number.

Amateur's Hand-Book.

TO save disappointment, it may be well to notify our readers that the "Workshop Companion" contains *all* the matter that is found in the "Amateur's Hand-Book." Those, therefore, who buy the "Workshop Companion" do not need the "Hand-Book."

Work and Luck.

MOST people like to be astonished and to have their faculty of wonder excited, and nothing excites this feeling more than the contemplation of a result, the causes of which do not seem to be sufficient. When we see, for the first time, a weak man raising a heavy weight by means of a lever, we are struck with wonder, because, it does not seem possible that the use of a slender bar can add so much to the man's strength, and when we see a pressure equal to many tons exerted by the forcing in of a little water into a cylinder, we have the same feeling.

We all like to see and to hear of wonderful things. But when we come to understand the causes which produce the results which have astonished us, we no longer wonder. We find that in every case the cause and the effect are precisely equal, and we use levers and hydraulic presses without being in the slightest degree surprised at the effect produced by

them. What is true in mechanics, is true of mind. Every result is produced only by a sufficient cause, and we never find that any one becomes an expert without long and earnest work.

Literary men who wish to make their writing more pleasing than instructive, are very apt to pander to the feeling of pleasure which we all take in wonderful stories, and they have filled the history of science with fables in which they tell us that almost all great discoveries were the result of accident. Thus we are told that the Galvanic battery owes its origin to some frog's legs, prepared for soup for Madam Galvani, and hung on an iron railing. The wind blew and moved the legs away from the metal, and then allowed them to fall against it again, and every time they touched the iron they gave a convulsive twitch. Galvani saw it and invented the galvanic battery.

This whole story is a fable. At the time spoken of, Galvani had been engaged for years in experimenting on animal electricity, and had often used frog's legs as electroscopes, but in spite of all this, he did not invent the battery which was devised some years after Galvani's death, by Volta, and should be called the *Voltaic*, and not the *Galvanic* battery.

The same class of writers tell us that Newton was led to his famous discoveries by the falling of an apple as he sat in his garden. The most careful research fails to find any ground for this story. Newton was engaged for years in working out his famous discoveries ; he was not led to them by any accident, but by honest hard work.

Another story is that told of Galileo, that he invented the pendulum from seeing a chandelier swinging in a church. Pendulums had been used long before his day, and at the time he saw the chandelier he had been studying the subject for years, and merely used it as an illustration of the great laws which he was endeavoring to work out.

Another story is that of Watt, who is said to have invented the steam engine from seeing the steam lift the lid of a kettle as he sat by his mother's fireside. Now it happens that steam engines were in extensive use in Great Britain long before Watt was born, so that the power of steam was well known. Watt, however, made a careful study of the properties of steam, and experimented upon the subject until he was familiar with all the facts in the case. After this hard work and experimenting, he was able to so improve the steam engine of his day that his fame will last as long as our modern civilization endures.

The lesson to be drawn from all this is, that if we would succeed, we must depend upon good hard work and not upon luck. Luck rarely does much for any one, and if we wait for accidents to help us, we may wait in vain for ever.

Designs for Scroll-Sawyers.

MR. HODGSON, whose admirable articles on scroll-sawing are now in course of publication in the YOUNG SCIENTIST, has prepared for us a series of seventeen designs covering a great variety of subjects suitable for Christmas presents and ordinary articles of household ornament and utility. These designs we have had photo-lithographed and printed on two large sheets. They are full size and embrace over eighty different pieces. Knowing that this set must have a large sale, we have placed the price at 25 cents for the set, or a cent and a half for each design. We know of no designs equal to these which can be had for less than five, ten, or twenty cents each.

To any boy or girl who will send us a new subscriber to the YOUNG SCIENTIST (together with their own subscription) we will send a set of these designs free. The subscriptions may be for 1878, 1879, or 1880. Remember, one of the subscribers must be new. It will not do to send a renewal of the subscriptions of two old subscribers.

BOOK NOTICES.

Laboratory Teaching: or, Progressive Exercises in Practical Chemistry. By Charles Louden Bloxam, Professor of Chemistry, in King's College, London. etc., etc. Fourth Edition, with Eighty-nine Illustrations. Philadelphia: Lindsay & Blakiston.

This is a most excellent little book, clear and full on all those points in which the beginner re-

quires instructions. It gives full directions for the performance of such operations as are required to illustrate chemical principles, and also gives directions for analyses. Students who desire to get a book which will help them to a knowledge of practical chemistry, cannot select a better.

The Boston Journal of Chemistry. Devoted to the Science of Home Life, the Arts, Agriculture and Medicine. $1.00 per year. Boston Journal of Chemistry Co.

This able and interesting journal is now in its fourteenth year, and every season it grows better and better. To those who wish a wide awake journal which gives a view of recent scientific progress, without making any heavy demands upon purse or time, we would recommend the *Boston Journal of Chemistry.*

GEOGRAPHY OF THE MOON.

We herewith begin a series, as indicated by the heading, upon the natural divisions or surface of our satellite. We shall confine our observations to a class of objects which may be easily seen with small telescopes in the hands of amateurs.

The Moon is the easiest of all celestial objects, being only about 240,000 miles distant, and subtending an angle of about one-half of a degree. Ever since the time of Galileo, who first discovered the mountains and valleys on its surface, the Moon has been the object of unceasing observation. Amateurs were, however, debarred from a careful and comprehensive study of lunar geography by the lack of a good map, adapted to their purposes. This want was supplied in 1859 by the Rev. T. W. Webb, who reduced "Mappa Selenographica," which was originally issued in four large sheets, and omitted a vast amount of detail, such as would only tend to confuse and discourage the beginner. The work with which that map was issued ("Celestial Objects for Common Telescopes") has long since been out of print, and is now costly and hard to procure.

The Editor has prepared the way for a rich feast for the student of Astronomy, by faithfully reproducing this map in full.

In order to avoid crowding on the map, each object is numbered, and in referring to them we will give the name by which it is known, and in parentheses the number by which all may be, in time, identified and observed under the most favorable circumstances.

It will be noticed that, as in terrestrial maps, North is at the top and South at the bottom of the map, but East and West are reversed; that is, East is at the *left* and West at the *right*. Hence, when observing the Moon and using a terrestrial eye-piece, it will appear as represented in the map; but while using an inverting eye-piece and comparing, the map should be inverted, so that S. will be at the top and N. at the bottom, then W. will be at the left and E. at the right.

The First Meridian and Equator are the only great circles represented, and these divide the map into four quadrants, which are called the 1st or NW., 2d or NE., 3d or SE., and 4th or SW., Quadrants.

Nothing is to be gained by the use of high powers. A good telescope, with a clear aperture of three inches, ought to bear a power of 450, and it will be found that nothing can be gained by the use of higher powers. Indeed, for most purposes in lunar observations, a much lower power is preferable.

Very much depends upon the age of the Moon at the time of the observation, as many remarkable features which are plainly visible at certain times or at a particular age of the Moon, are either wholly invisible at the full or are very unsatisfactory. Hence, in future articles, we will instruct as to when to look for these things.

It would be well to mount the map upon a piece of firm cardboard large enough to leave a margin of two inches all around, so as to have it in convenient shape for reference, and not damage it with finger marks.

The writer will give careful attention to all letters of inquiry regarding telescopes, etc., which may be suggested by these articles.

Penn Yan, N. Y.

Correspondence.

A Cheap Telephone.

Ed. Young Scientist—To make a cheap and serviceable telephone good for three blocks or so, only requires enough wire and two cigar boxes. First, select your boxes and make a hole about half an inch in diameter in the centre of the bottom of each, and then place one in each of the houses you wish to connect, then get five pounds of common iron stove pipe wire—you can take back what you don't use—make a loop in one end and put it through the hole in your cigar box and fasten with a nail; then draw it *tight* to the other box, supporting it when necessary with stout cord. You can easily run your line into the house by boring a hole through the window sash, or cutting a hole through the glass. Support your boxes at their ends with slats nailed across the window, and your telephone is complete. I have one that is two blocks long, and cost forty-five cents, that will carry music when the organ is played thirty feet away in another room. There are quite a number of lines like this in town. HARRY HOLDEN.

Black Earth, Wis.

Examining the Bottoms of Ponds and Rivers.

Ed. Young Scientist—In the last issue of the YOUNG SCIENTIST, there is a very interesting article on the use of mirrors for examining the bottoms of wells, ponds, and rivers. I have used mirrors for this purpose, and can endorse all that is said of them. In the case of ponds and rivers, however, something more is needed as the reader will find if he tries. Some years ago, while fishing in a somewhat deep lake from a boat, I had the misfortune to lose a valuable little rifle. We marked the place pretty carefully, buoyed it, as I believe the sailors call it, and tried to work out some plan by which it might be recovered. We even had thoughts of employing an expert swimmer to dive for it, but could not find one in the neighborhood. In this dilemma our old Professor of Natural Philosophy (of Physics he called himself,) came to our aid. He never was happier than when helping us boys, provided he could teach us at the same time, and you may readily believe that under such circumstances we were glad to learn. The Professor armed himself with a large mirror (it was at least two feet long and of proportionate width), a thick horse blanket, a large hoop from a hogshead, a powerful compound magnet, and some stout cord. When we reached the spot in the boat, the buoy was still there, and we anchored as close to it as possible.

The Professor tied the magnet to the cord, and arranged the blanket over his head so that the ends dipped into the water and excluded all light except what came *up through* the water. The hoop enabled him to form a sort of tent, so that he had room to work. We had, of course, chosen a bright day, but alas for Old Probabilities, it clouded up just as we got afloat. This, however, did not seem to disconcert our Professor. His original plan had been to throw the sun's rays to the bottom of the lake by means of the mirror, and he, being in total darkness, except for the light coming from the bottom of the lake, would be enabled to see any object lying there. Now, however, he took from his pocket a bit of magnesium ribbon, and we set it on fire outside his tent Of course we held it so

that it lighted up the bottom of the lake, and to add to the brilliancy the mirror was held so as to throw down all the rays possible.

After two or three trials in different places we heard the Professor exclaim "I see it, steady boys!" and steady it was. The magnet was lowered, a little more magnesium was burned to enable the Professor to adjust it properly, and up came the rifle.

On the way home the Professor told us that if the water had been rippled the blanket dipping into it would have kept a still place. If too rough, he could have made a water tight tube in two divisions and with a glass bottom. Down one division he could have sent the light, while he looked through the other.

Sunlight, of course, is best, but when sunlight is not to be had, magnesium is a very good substitute, and where magnesium cannot be had, a light may be made by filling a paper tube with blue light mixture* and burning that. The materials may be had in any country drug store

AN OLD BOY.

Plaster of Paris.

Before the establishment of cement mills, plaster was only used by stucco men, and these had generally to prepare it for their own use; the gypsum was never burnt, at least by those who did fine work; the term was "boiled," not "burnt;" the raw gypsum was pounded and sifted, and the water of crystallization was driven off in an open pot or pan, the powder being stirred the while; during which operation it assumed all the appearance of a fluid, owing to the rapid escape of the steam) especially from the lower stratum, which kept the whole mass alive, so that when the surface was disturbed it immediately assumed its own level. When all the water was expelled this peculiarity ceased, the gypsum was given a good heat, so as to make sure of its being thoroughly dried, but not by any means to burn it or let it get red-hot, which was reckoned to spoil it, as if overheated it set too quickly, or merely acted as common lime.

In mixing for use, plaster ought to be added to water, not the water poured on to the powdered plaster. And if any coloring matter be used, such as red ochre, it ought to be first mixed with the water, so as to insure equable distribution; if a hard material be required, add alum or sulphate of sodium (Glauber salts) to the water. These cause the plaster to set with great rapidity, but should it be wished to delay the setting, mix with a weak solution of glue or gelatin. The stucco men use this in order to give time to trim mouldings, etc. For fine work the plaster may be sifted again after being boiled. It may be kept for any length of time, if kept perfectly dry and in a place or vessel where it cannot imbibe moisture from the atmosphere. Should this take place, no boiling or burning will again revive it.—*English Mechanic.*

* Directions for making all kinds of lights will be found in the "Workshop Companion."

How to Loosen Screws.

Few things are more vexatious than obstinate screws, which refuse to move, much less to be drawn out, and in the struggle against screw-driver power suffer the loss of their heads, like conscientious martyrs, rather than take a single half-turn backwards from the course they have followed, and from the position they have been forced into. Like obstinate children, they must be coaxed, or rapped pretty hard on the head, according to circumstances; in fact, whoever has a tight, obstinate screw, to "draw out," must keep his temper down and his resolution up, quite as much to the sticking-point as the screw does. If the screw is turned into iron and not very rusty, it is only necessary to clear the head with the wedge of the driver, and let a few drops of oil penetrate to the threads; but, finding that excessive heat or rust has almost fixed the screw immutably, then heat, either by placing a piece of hot iron upon it or directing the flame of the blow-pipe upon the head, and, after applying a little oil, turn out gently; but care must be taken not to let the tool slip so as to damage the notch. If, however, the screw refuses to come out, try to force it back with a blunt chisel, smartly but carefully tapped with a light hammer; but if evidently nothing can dislodge the enemy, it is best to cut the head away and drill out the screw. When an obstinate screw happens to be in wood, merely give it a few taps on the head; but failing that, heat it with a piece of hot iron, when it may be easily turned.

Practical Hints.

Keeping Mice From Seeds.—Any one desirious of keeping seeds from the depredations of mice, can do so by mixing some pieces of camphor gum in with the seeds. Camphor placed in drawers or trunks will prevent mice from doing them injury. The little animal objects to the odor, and keeping a good distance from it, he will seek food elsewhere.

Marking Tools.—Much trouble can often be saved by marking tools with their owner's name, which can be easily done in the following manner:—Coat over the tools with a thin layer of wax or hard tallow, by first warming the steel and rubbing on the wax warm, until it flows, and let

it cool. When hard, mark your name through the wax with a graver and apply aqua-fortis (nitric acid); after a few moments, wash off the acid thoroughly with water, warm the metal enough to melt the wax, and wipe it off with a soft rag. The letters will be found etched into the steel.

Transferring Pictures to Glass.—Coat the glass with a varnish of balsam of fir in turpentine, then press the engraving on smoothly and evenly, being careful to remove all air-bubbles. Let it stand for twenty-four hours, then dampen the back sufficiently to allow the paper to be rubbed off by the forefinger, rubbing it till a mere film is left on the glass, then varnish again.

Cementing Glass to Metal.—A great deal of difficulty is experienced in cementing metal to glass. The *Faerber Zeitung* says that a mixture of two parts finely ground litharge and one part white lead, and working it up to a stiff paste with three parts boiled oil and one part copal varnish, adding more litharge and white lead as required, is the best material for joining the two substances.

Phosphorescent Powders.—A powder which after being exposed to strong sun-light, continues to emit light in the dark and so serves to render barometers, compasses, etc., luminous, is formed thus: Grind and ignite a mixture of 100 parts carbonate and phosphate of lime (obtained by the ignition of shells, especially *Tridama* and *Sepia*) with 100 parts quick-lime, 25 parts of calcined salt, and 25 to 50 per cent of the whole mass of sulphur. Then add 6 to 7 per cent. of a coloring matter—a sulphide of calcium, strontium, barium, magnesium, aluminum, etc. This powder is particularly phosphorescent under the influence of an electric current.

To Prevent Rusting.—1. Boiled linseed-oil will keep polished tools from rusting if it is allowed to dry on them. Common sperm oil will prevent them from rusting for a short period. A coat of copal varnish is frequently applied to polished tools exposed to the weather. Woolen materials are the best for wrappers for metals. 2. Iron and steel goods of all descriptions are kept free from rust by the following:—Dissolve ½ oz. of camphor in 1 lb. of hog's lard, take off the scum, and mix as much black lead as will give the mixture an iron color. Iron and steel and machinery of all kinds, rubbed over with this mixture, and left with it on for 24 hours, and then rubbed with a linen cloth, will keep clean for months. If the machinery is for exportation it should be kept thickly coated with this during the voyage.

To Make Badly-fitting Blinds and Doors Shut Tightly.—When blinds and doors do not close snugly, but leave cracks through which drafts enter, the simplest remedy, recommended by Mr. Schuetse, building commissioner in Dresden, Germany, is this: Place a strip of putty all along the jambs, cover the edge of the blind or door with chalk, and shut it. The putty will then fill all spaces which would remain open and be pressed out where it is not needed, when the excess is removed with a knife. The chalk rubbed on the edges prevents the adhesion of the putty to the blind or door, which can then be opened without adhesion, and the putty is left in place, where it soon dries and leaves a perfectly fitting jamb. Any smart boy can do this.

EXCHANGES.

Wanted, a cornet; must be in excellent order, state what is wanted in exchange. James B. Athearn, New Bedford, Mass.

Wanted, Archæological relics and fossils, for butterflies, beetles, spiders, etc. Correspondence invited. A. W. Baily, Box 195, Pottstown, Penn.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho,

Telegraph instruments with 400 feet of wire and battery, it cost $12; will exchange for scroll saw, or offers. F. Cushing, Wattsburg, Erie Co., Penn.

An improved camera lucida for drawing, etc.; also, a printing press, chase 2½ x 3½, for offers. L. De Veau, 87 E. 10th St., New York.

What offers for a magnificent black walnut mineral cabinet, 5 ft. x 4 ft., desk form, and double, has 4 glass doors, 12 drawers, veneered panels, with drop handles, massive carved legs, and is lined in blue, cost $80 cash. W. L. Farnum, Owosso, Mich.

Postage stamps, spectograph, drawing cards in case, sketch blocks, size 12x20 and 9x12 in., one book, "No Alternative," for minerals, coins, birds eggs, Indian relics or offers. Frank F. Fletcher, St. Johnsbury, Vt.

To exchange: well-mounted slides of hair and fur, for other well-mounted slides of same, lists exchanged. Address, W. Hoskins, 208 S. Halstead St., Chicago, Ill.

Rare insects, minerals, and shells, in exchange for scientific books. P. W. Lee, 310 Marlborough St., Boston, Mass.

A set of carving tools worth 75c.; card stamp and type worth $3.00. State offers, magic lantern preferred. Address Frank H. Libby, Saco, Maine.

A first class sewing machine will be exchanged for books or offers. Address, Lock Box, 22 Schoharie, New York.

Gaskel's compendium, and Virgil's works translated by Dryden. State offers. G. Osgood, Jr., Abington, Mass.

Cocoons of attacus cecropia or mounted specimens of Lepidoptera to exchange for the following cocoons: "A. Luna," "A. Prometheus," "Saturnia Io," a "Ceratomia quadricornus." R. Perry, 50 E. Washington St., Indianapolis, Ind.

Wanted, in exchange for one vol. of "The Boys of New York," or the "Young American," a two line card printer with type and everything complete. Address, W. H. Pretty, Bellville, Ont., Canada.

Wanted, to exchange, Lake Superior copper specimens for type. T. J. Prince, Houghton, Mich.

For exchange, a small lathe, (foot power), 2 sewing machines, 1 Wheeler & Wilson, 1 Singer, medium, in good order, but little used; wanted cabinet makers tools, tent, or scroll saw. R. P. Wakeman, Southport, Conn.

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, MARCH, 1880. No. 3.

Horn, and How to Work It.

OF late years horns of great size and excellent quality have become comparatively common in many of our large cities, and are, therefore, not difficult to procure. Our young friends can make a great variety of useful and pretty things out of them, and therefore a few hints concerning the best methods of working this material cannot fail to prove acceptable. In the arts, horn is used for a great variety of purposes. First of all we have the traditional use to which horns were first put, viz.: musical instruments—and although "horns" are now made of anything but *horn*, still it is a fact that the hunter of old generally used the horn of the wild bull or buffalo as an instrument by which to call together his companions, or to indicate to them, by certain prearranged signals, the character and direction of the chase.

In the olden times drinking cups were generally made of horn, and even now the phrase "taking a horn" is used metaphorically for taking a drink. Amongst other household articles made of horn were spoons and shoe-horns, or shoe-lifters, both of which are now generally made of metal. Of the fact that spoons were made of horn a memento still exists in the proverb—"I will make a spoon or spoil a good horn."

Before the days of metallic cartridges and powder flasks, powder was carried in horns, and powder flasks are still sometimes called "powder horns." It is not many years since most combs of the cheaper and commoner kinds were made of horn, and the finer and clearer specimens of this material were used for making boxes and frames, and cases for magnifiers and other optical instruments. Mathematical instrument makers also use thin sheets of horn for making protractors, and templates for irregular curves. These thin sheets have long been used for making lanterns, or lanthorns (*lamphorns*) as they are sometimes called, but of late years mica has taken the place

of horn, being more transparent and much cheaper.

The best horns come from South America. The Cape of Good Hope and the East Indies also yield a large supply of very excellent horns. Of late years the Texan herds of cattle have furnished large quantities, but other materials, such as vulcanite and celluloid, that are more easily worked, and that give better results, have lessened the demand, and consequently rendered them less valuable.

Horn consists chiefly of hardened gelatine, and although it cannot be reduced to glue by boiling, it can be softened by heat so as to be readily moulded into almost any form. The horn, as it grows on the animal, consists of concentric layers of this peculiar material, which are cemented together with a firmness that varies at different parts of the horn. Thus, at the base or part next the head, the layers are easily separated, and consequently the horn is loose and easily split at that part. On the other hand the tip is so hard and solid that it is very difficult to split, and hence is used for such work as making the tips of bows, etc.—purposes which require very hard and tough material. A knowledge of the different qualities of the different parts is necessary to those that would work this material successfully.

In preparing horns to be worked, the first step is to free them from everything except the pure material known as horn. This is most easily done by steeping or macerating the horns in water. This process requires nearly a month; the horn itself does not putrify, but the cores and other parts do, and are then easily separated. The horns are then thoroughly washed in weak lye (not soaked, however) and are ready for the next process, which will depend upon the purpose for which the horn is wanted. Thus the horn may be used whole, as for musical and sound-giving instruments, powder horns, etc. Or it may be left in its original form, but used in parts, as for drinking cups. Or it may be formed into flat plates as for combs, or thin sheets for lanterns, or it may be moulded into such objects as boxes, cups, etc. And the best way to tell our readers how to go work will be to take up these different objects, one by one, and tell how each is made.

Let us suppose, then, that the reader has a fine specimen of horn, out of which he wishes to make a powder flask. The first thing will be to decide as to the mountings. If he intends to pursue the old plan he will simply plug the large end, bore a hole through the tip or small end, and use a neatly-carved or turned plug of bone or wood as a stopper. In this case the powder is simply poured out into a measure or into the hand and transferred to the gun. Amongst the Seminole Indians an alligator's tooth used to be a favorite powder measure.

If, instead of a simple plug, a metallic mounting should be preferred, then the best plan is to procure a good spring top, such as is used on the best metal flasks. Such tops might perhaps be procured through some gunsmith from the manufacturers. The horn must then be cut off at the tip end, a little *above* the point at which the diameter of the horn is the same as that of the mounting. It can afterwards be cut off so as to fit exactly.

Provision must also be made for attaching rings by which the horn may be suspended by cords. These rings must not be screwed or riveted into the horn, as the beauty of these flasks is their excessive thinness and lightness—the grains of powder actually appearing distinctly through the sides. This renders the horn very slight and delicate, and the only way to attach the small rings for the cord is by means of two large, thin rings or ferrules, which go entirely round the horn and are prevented from slipping off by means of two or three rivets. These large rings may be of silver or, what is better, of brass or steel, heavily nickel-plated. Silver is easily discolored by gunpowder, while nickel is not.

Having arranged for the mountings, the next step is to prepare the horn. If the tip is to be left on, the upper end of the horn is hollowed out by boring with a half-round bit. If the tip is cut off so as to leave a large hole in the upper end, the inside of the horn is finished by scraping. The inside must be well scraped, so as not only to remove any membranes left after

the core has been taken out, but to make the inside quite smooth and polished, as upon this the beautiful transparency of a well-made powder horn chiefly depends. Consequently, while we may use files and riffles for the beginning of the work, we must soon give them up for a steel scraper made out of a bar or rod of steel, of which the end has been bent square and properly ground and sharpened. The edge of the scraper should be very sharp and finely finished on an oilstone. It will not do, however, to depend upon the scraper altogether, as this tool is very apt to work the material into ridges or *utters* as they are called. Bent files, called *riffles*, must be used for *straightening* the surface, and the scraper must be confined to its proper office of smoothing. The same process must also be applied to the outside, which must be worked down until the surface is perfectly even.

In the meantime care must be taken to leave the lower end of the horn so thick that a groove may be cut in it to receive the bottom. In the common horn flasks the bottom is made of wood simply fastened with tacks or screws, but this makes an unsightly finish. The proper way is to cut a circle or disk of horn out of a flat piece, and fasten this in a groove, which is done as follows: The end of the horn having been cut off square and even, a groove is cut round the inside at a very short distance from the edge—say one-eighth of an inch. To cut the end square take a piece of paper with a straight edge, wrap this round the horn, mark the line with a fine pencil, and cut off the horn with a fine, sharp saw. The edge is made perfectly smooth and straight by means of a small plane, for which purpose the little cast-iron planes, now so common, are excellent. The groove is cut by means of a tool like a cooper's croze or carpenter's marking gauge. The gauge has, instead of a point, a hook-shaped cutter, which cuts a clean but not very deep groove round the inside. The flat disc is then turned up in the lathe so as to have a ridge on the edge, this ridge just fitting the groove. The disc is made a very little larger than the opening into which it is to fit, and the latter is expanded by plunging the horn for a few minutes into boiling water. The horn softens and expands so that the disc is easily forced into its place. When the horn cools it shrinks on the disc so as to make it very firm.

Before fastening the disc in its place, however, the surface of the disc and the inside of the horn should be finely polished. This is neccessary for the purpose of rendering the flask transparent, for no matter how thin the horn may be scraped it will not be transparent unless it is finely polished. This is seen in glass, very thick plates of which are quite transparent when the surfaces are polished, but lose this quality when the surface has been ground or slightly roughened.

Horn is polished by being first smoothed by means of the steel scraper; then it is worked with the finest pumice-stone or rotten-stone, and oil or water, a piece of leather being used as a rubber; after this it is polished by means of fine, washed putty powder mixed with water or oil, and rubbed on with cloth or leather. The very finest finish is given by rubbing with the naked hand in the same way that tortoise-shell and papier mache are polished.

After the inside has been polished and the bottom fastened in, the projecting edge of the horn is rounded and the entire outside is polished by the same process that has been described for the inside.

Previous to the polishing of the outside, the mountings should be carefully fitted to their places, and in the case of horns which are not cut off pretty well down, the outside should be polished and the rings riveted on before the bottom is put in, as it will be impossible to do it afterwards. When a spring top is to be attached the opening will be large enough to allow of the riveting of the rings *after* the bottom has been fastened and the horn polished. No grooves should be cut for the rings. They should simply be driven on tightly and fastened with one or two very slight rivets.

The top may be screwed on, or fastened in any other way that will make a good job. As, however, our object is to tell how to work *horn*, it is unnecessary to describe them. In our next article we will tell how to work horn into other forms and articles.

Home-Made Telescopes and Microscopes.—III.

CUTTING AND ROUGHING OUT THE GLASS.

WHEN ordinary plate glass is used for simple lenses it is generally cut into squares by means of a common glazier's diamond, and these squares are worked into shape either by grinding or by means of a pair of soft pliers. The pressure of the pliers, applied near the edges of the glass, cause it to crumble away in small fragments, and the process, which is called *shanking* or *nibbling*, is continued until the pieces are made circular and of a diameter a little larger than the finished size of the lenses. If we wish to make a plano-convex lens and it is found, after careful examination, that the surface of the plate glass is sufficiently smooth and even to answer without further grinding or polishing, this surface should be protected from scratches by having a piece of paper pasted over it. After the glass has been roughed out to nearly the right size, the paper should be soaked off and the plane side of the glass cemented to a metal or wooden handle. The cement will protect the surface.

If, however, the lenses are to be ground out of discs or blocks of glass, such as are sold by the dealers in optical glass, then a different plan must be pursued. Glass of this kind is too costly to be wasted by breaking it into irregular fragments; it should be sliced into plates of proper thickness by means of a lapidary's slitting machine. This is simply a disc of thin sheet iron which is mounted on a mandril and turned up true and smooth. It is of importance that the edge of the slicer should be quite true and free from even minute notches. In the usual lapidary's slitting machine, the slicer runs horizontally, but it may just as well run vertically and so be used in a common lathe.

To charge the edge of the slicer, or to *season* it, as it is called, requires some care. The diamond powder is easily procured from dealers in fine tools, and should be quite fine. It is mixed with a little oil in a small glass cup or pot provided with a cover. To apply it to the edge of the iron disc, a little is taken up on a small spoon made out of a quill, and the hollow of the quill, holding the diamond powder, is held against the edge of the slicer until the latter is coated. The diamond particles must now be forced into the metal, and this is done by holding a flat piece of hard stone, such as agate or flint, against the edge. Care must be taken not to allow the slicer to cut into the flint or agate, as this would force particles of diamond into the sides of the slicer where they are not wanted. As soon, therefore, as the slicer begins to *cut* the stone it must be shifted to a new place. As soon as the small quantity of diamond resting on the edge of the slicer has been forced into it, the margin of the slicer is carefully wiped on both sides with the forefinger, in order to remove any small portions of the diamond that may have become accidentally lodged on the sides, and these particles are pushed to the edge of the slicer and pressed in with the charging stone. After the edge of the slicer has been once fairly charged with the diamond powder, a single application is generally sufficient for restoring the cutting edge, and under the hands of the practical lapidary a single seasoning will endure several hours work.

We have given these directions because professional lapidaries are inaccessible to most of our readers. Where the worker wishes to get along with cheaper and simpler means, the following directions by Mr. Wenham will be found valuable:

"Pieces of glass may be readily sliced with a circular disc of soft iron, running in the foot-lathe, and fed with flour emery and water; the edge of the slicer must be frequently notched with the sharp angle of an old file. The sample of glass or mineral is cemented to the end of a staff, and held preferably in the slide-rest. If the screw of the rest is taken out and the slide made slack, the work can be thrust up to the slicer with the pressure of the fingers, and there is less risk of fracture from undue violence. The sliced glass is cut into squares, a little exceeding the diameter of the intended lenses, by means of a glazier's diamond, and the corners rounded off with a pair of optician's

"shanks" or nibblers, which are a species of pliers, made, in preference, of soft iron, as this grips the glass without slipping, as hard steel would do. This instrument, of a larger size, is capable of removing slivers of glass from the edges of a plate upwards of one inch in thickness.

"All glass is much softer than hardened steel; but if this is set to cut in a dry state, the heat generated at the working or abrading point softens the cutting edge, and speedily destroys its action; but if some turpentine is applied, this quite prevents the softening of the tool. In the lathe, or with a common Archimedean drill, holes may be drilled through thick plate-glass with surprising rapidity, if kept well bathed in turpentine. Masses of glass may also be turned in the lathe with a steel tool, if plentifully supplied with turps, and run at a moderate speed.

"The first experimental parabolic condensers were made from plate-glass 1½ inches thick; pieces of this nibbled rudely to form, were cemented on to a chuck. The T-rest was next placed nearly on a level with the top of the work, and an old triangular saw-file, kept sharp *on one side only* by repeated applications to the grindstone, was then held on the rest, so as to attack the revolving glass slantways, or spoke-shave fashion, with plenty of turpentine. By these means the glass was quickly reduced to form, so as to fit the template; and the ridges left by the file were swept away by means of small leaden laps, fed with emery and water of increasing fineness. The polish was obtained by a rubber of willow-wood, cut crossways of the grain, used with crocus (peroxide of iron) and water, and at last a lump of beeswax with very fine crocus was employed for the final polish.

"For working small concave lenses, as nearly as possible to their final form, a great deal of accurate and skilful turning is required. For this delicate work steel tools are quite unsuited, and diamond points are invariably used. The common practice of mounting these has been to solder them with brass and borax, by means of the blow-pipe, into the end of a steel tube about the size of a watch-key, leaving a hole behind to prevent the diamond from being blown out during the fusion; but I have never found this method secure for small splinters. The brass has really no affinity for the diamond, but rather tends to avoid it; and this is frequently only held in by the glaze or flux. The loss of several diamonds induced me to abandon this practice, and since adopting the following mode I have never lost one.

"I take a piece of copper wire, about 1-12th of an inch thick, and drill a shallow hole in the end, of the size and depth required to contain the diamond, Fig. 4. A

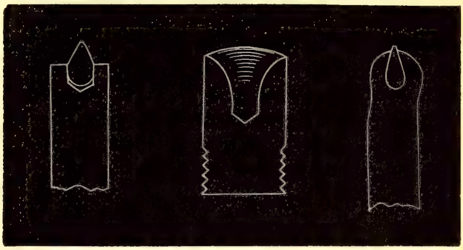

Fig. 4. Fig. 5. Fig. 6.

piece of steel, turned out with a bell-mouth, and hardened, is shown in Fig. 5. This is spun rapidly in the lathe, a drop of oil is applied, and the end of the copper rod containing the diamond is pressed hard in, at the same time giving it a slight rolling motion. Speedily the copper is compressed tightly round the diamond, as in Fig. 6, which becomes very firmly imbedded in the soft metal; and if the operation is carried too far, the copper rises over the point and completely buries the splinter.

"By mutual abrasion, the diamonds rapidly grind each other away, and two, mounted in wires in this way, may be kept mutually to a sharp point by chucking one in the lathe and using another as a turning-tool. In employing these diamonds for turning glass, no particular directions are needed; they seem to cut rather better if the work is kept slightly moist.

"The most convenient way, for the amateur, of reducing the substance, or giving the rough rounded form to small lenses, is a large plate of zinc and coarse emery and water; iron is too hard, lead too soft, and copper poisonous."

Parallel Pieces and Parallel Strips.

BY JOSHUA ROSE, M. E.

PARALLEL pieces for lathe work are pieces of metal of parallelogram form, employed to hold work away from, but true with, the lathe face-plate. Parallel strips are similar pieces (usually of steel) having bolt holes so that they may be made to grip the work.

In the accompanying illustrations the employment of both these useful devices is shown. A, A, are a pair of parallel strips containing the brasses, B, B, and clamping them because of the bolts, E, E. A, A, rest upon the parallel pieces, C, C, the whole being clamped to the face-plate by the bolts and plates, D, D.

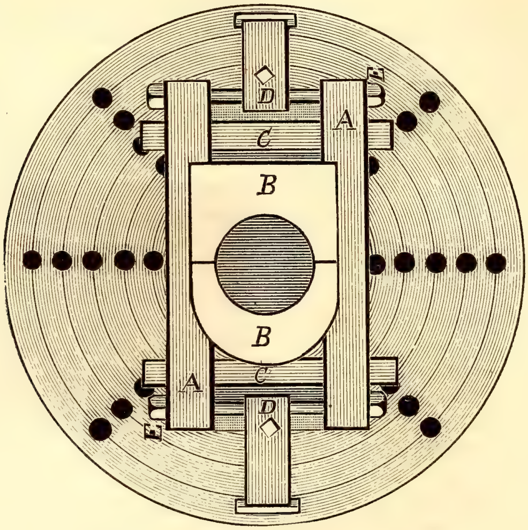

Fig. 1.

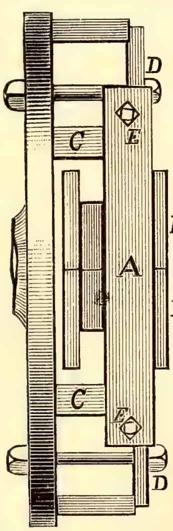

Fig. 2.

By this means the brass can be bored true to the inside faces of the flanges (which are true because they have been fitted to the strap to which they belong), which rest against the faces of A, A, the latter being kept true by the parallel pieces, C, C. The back faces of B, B are held clear of the lathe face-plate while the front faces are free and clear for turning. Care must be taken to tighten up the bolts, E, E, alternately and equal, or one brass may be gripped tighter in the strips than the other, and the latter would hence be liable to move from the pressure of the cut.

—The smallest circular-saws in use are those employed in making gold pens, and are only half an inch in diameter.

Skin Preserving.

JUST at this time of year, when the "close season" is in abeyance, and when pottering round the hedgerows for the chance of a rabbit, one occasionally meets with feathers or fur worth preserving, I have been several times asked for hints as to making up skins, till a competent stuffer, a rarity, unluckily, can be met with; and not being without experience of my own as to the difficulty of the matter, perhaps a few simple hints which may assist in overcoming the first difficulty—the *premier pas qui coute*—may be useful.

With a little practice, a bird's skin can be removed from the body as easily as that of a quadruped, and with a much more satisfactory result, as in the one case there is a thick coating of feathers which will make up for any slight deficiency in the perfection of the skin itself, while, in the latter case, the greatest possible care must be taken not to stretch the skin in the least; or a bare patch, which no amount of art will cover, will be the result. So that premising that the method of skinning is in both cases precisely the same, it will be as well to take the easier subject, the bird, on which to commence.

By "making up a skin," is understood so arranging and preserving it that a professional taxidermist will have no difficulty in softening and setting it up, after a reasonable lapse of time, while the plumage of the bird is preserved, as nearly as possible unruffled, in the ordinary position when dead.

The tools required are, I had almost said, none; but nothing more than a penknife is necessary, while a stout pair of pointed nail scissors are more handy for cleaning, and by no means cumbrous. Taking the bird as it lies, yet untouched, it is better to leave any dried blood stains to be removed after skinning. There is no advantage in cleaning at once, as after removal the feathers can be grasped from within, as well as from without, and there is less chance of stretching, the thing to be guarded against throughout, Any wet stains had better be removed at once with a bit of sponge, as they will be infinitely more troublesome when dry.

Having disposed of stains, notice where there are any wounds in the skin, for future guidance; one is very likely to increase a rent if it is unexpectedly come upon. Then take the bird by the beak, and smooth down the feathers with the free hand; placing the bird carefully on its back when every thing is in place.

The next step is to prepare the way for skinning the limbs. Taking the leg by the "knee," where the bare shank meets the feathers, and by the bone just above the joint, the leg is snapped—taking care that the pointed ends of the bone do not injure the skin—just within the commencement of the feathered portion. The same is done with the wings, and the ruffled feathers are replaced.

If the thick feathers covering the breast are now separated, a broad bare space will be found running the whole length of the body. Along this line an incision is made with the penknife, from the projecting end of the breastbone to the arms; then keeping the feathers as much as possible from the edges of the cut, though, if carefully made, there is not the least bleeding from the breast, and the special covering of the intestines is not cut through. The skin is separated with the back of the knife from the sides as far as possible, without lengthening the incision. Then carefully working down by the side of the abdomen, the legs are reached; the skin is turned back till the broken bone is found, and the muscles cut through; freeing the skin of the leg, and leaving only the broken bone end in the pocket formed by the removal of the "drumstick." The other leg is treated in the same way.

The connection of the arms with the abdomen must next be severed, and the skin turned back to the tail; the attachment of the spine to the tail severed, and then the skin of the back is carefully—for owing to the thinness of the covering here, the slightest stretch will make a woful gap in the feathers—reflected till the wings are reached. These are treated in the same manner as the legs, and then the skin is entirely removed from the body, leaving only the head and neck to be completed. The neck is cut through at its junction

with the chest, as it and the head are treated separately.

So far this sounds like a very lengthy proceeding, but, in practice, the skinning of a whole body of, say a thrush, does not occupy more than five minutes, and there should not be more than the very slightest soiling of the fingers, if any, and none whatever of the feathers. Do not throw the body away, as it will be useful in finishing.

We now come to the head, which is the hardest part of the whole operation, since any stretching here, beyond what is unavoidable, must be very carefully guarded against. And, in mentioning this, it is well to remember that the skin should be supported during the whole process as much as possible, being allowed to rest on the tables, or on the knee, which, for myself, I prefer, as the weight of the feathers alone is enough to cause an awkward stretch in the thin backskin.

The head is cleaned by turning it backwards through the skin of the neck in most birds. Some of the waterfowl though must have a special slit made below the beak, to allow the skull to be turned through, but they are very few, and it is only a modification of the usual process.

Taking hold of the end of the neck, where it was severed from the body, the skin is gradually turned back till the skull is reached. The head is then steadied by grasping the back from the outside, and the skin gently pushed back over the smooth cranium till the eyes are reached. Then, grasping the exposed skull, the eyelids are detached from the orbit, and the skin turned forward to the commencement of the beak.

This leaves the head ready for cleaning, which is generally found the hardest part of the finishing process. I find that the best and quickest way, and one which answers exceedingly well, is to insert the point of the knife into the base of the skull as far forward as possible between the two halves of the lower mandible, passing it up to the roof of the skull, and then by cutting backwards along the sides of the lower mandibles to the back of the skull, removing the tongue and the whole attachment of the neck and its organs with about one-third of the skull, allowing the contents to be removed entirely. When the eyes are next removed, the anterior two-thirds only of the skull remain attached to the beak, and the whole is perfectly cleaned.—*Science Gossip.*

To be Continued.

Editorial Notes.

Something for Young Microscopists.

FOR some time past our stock of paste eels has been exhausted, and we have been unable to send them to those who asked for them. We now have a stock on hand, so that we can supply a small quantity to any of our subscribers that wish it. Those who call at the office should bring a small bottle, or tin or wooden box with them. Those who send by mail must enclose five cents in postage stamps to pay for packing and mailing.

These eels are exceedingly interesting and curious when seen under the microscope. For the benefit of our younger readers we give the following directions for managing and showing them: As soon as you have mailed your order for the eels, prepare some flour paste, well boiled and about as thick as cream. This will be in just the right condition when the eels arrive. The eels will come in the form of a little paste, packed in a hole in a block of wood. Take the block out of its wrapper, fill the hole with thin paste, and then put the block into a cup of paste, covering it over thoroughly. In a day or two the entire surface of the paste in the cup will be a mass of living eels.

To exhibit the eels proceed thus: Skim off a little from the surface of the paste and place it on a glass slide, adding a little water. Cover it with a thin glass and examine with a half inch, two-thirds, or one inch objective. The paste will be seen to be a living mass of eels. The light should not be very intense if the best results are desired.

A slide prepared in this way and illuminated by means of the spot lens, or paraboloid, presents a most beautiful and extraordinary appearance. The living creatures seem like brilliantly self-lumin-

ous or phosphorescent objects floating in a dark sea. Those who have not a spot lens or paraboloid may still get tolerably fair results by using very oblique light—light so oblique that the objective cannot take it in except when reflected from some solid object.

Having once obtained a stock of eels they may be multiplied indefinitely, so that a single speck is enough for all the microscopists of a large town.

Postage Stamps.

WE again call the attention of our subscribers to the fact, that while we take postage stamps of small denominations at full value, those of higher denominations are of no use whatever to us. We cannot sell them, except at a very great loss, and the post office will not exchange them for smaller denominations. Therefore, please do not send them.

Astronomy for Amateurs.

NEAR APPROACH OF THE MOON TO STARS AND PLANETS, ETC.

April 1. Moon 2° N. of bowl of "Milk Maid's Dipper.
" 6. " 20° S. of Great Square of Pegasus.
" 8. Jupiter 6° S. of Moon.
" 8. Saturn Conj. Sun—*invisible.*
" 8. Venus 7° S. of Moon
" 11. Neptune 6° S. "
" 12. Moon 5° S. of Pleiades.
" 13. " between Pleiades and Hyades.
" 14. " Apogee and Highest.
Apr. 14. " 5° S. of β Aurigæ, and nearly midway between Betelguese and Capella.
" 15. Mercury *very close* to Venus.
" 15. Mars 1° North of Moon.
" 15. Venus very close to Jupiter.
" 15. Moon 10° in Gemini: 20° S.W. of Castor and Pollux, forming an isosceles triangle.
" 16. " between Pollux and Procyon.
" 18. Jupiter very near Mercury.
" 19. Moon 4° South of Regulus.
" 20. Uranus 5° N. of Moon.
" 23. Moon very close to Spica.
" 26. Mercury gr. elon. W. 27°.
" 26. Moon Perigee.
" 27. " lowest.

THE MOON.—I.

The naked eye will show the freckled appearance of the Moon, and the smallest telescopes the numerous irregularities upon her surface. The observer must not think to make out the details at first; the eye must be practiced for the work. Neither should you expect to find a prototype of the earth, for our neighbor has no atmosphere. Hence, the denuding action of air and water are not at work there, and we see the lunar peaks in all of their primitive sharpness and ugliness, and as one gazes upon the scene, with a high power, the thought that we are gazing upon the scenes of gigantic convulsions, which must have shook that small body to its centre, cannot be repressed.

The following is the nomenclature of the Geography of the Moon: Mountains, Hills and Ridges; Gray Plains or Seas; Crater Mountains, composed of three classes—Walled or Bulwark, Plains, Ring Mountains and Craters; Valleys and Canals, or Rills.

Although a micrometer is not essential for interesting work, its use will add much to the pleasure of observing. One properly ruled into 60ths or 100ths of an inch may be procured of opticians for about $2.00. Insert it in the eye-piece, and it will be a simple matter to verify any of the figures which we shall give, and make independent measurements. Knowing the diameter of the Moon in miles, count the number of spaces required to make the diameter, then take such a part of the Moon's diameter as the spaces required to cover the object to be measured is of the entire number in the Moon's diameter.

The Grey Plains are known by the following names also: Sea, Mare, Lacus, Palus, Sinus and Ocean. The first one that we call attention to is *Mare Crisum* (A on the map). This is situated in the first or N.W. quadrant, and is best seen about 5 days after New Moon or 3 days after

Full Moon, or about the 14th and 27th of April. Mare Crisum may be seen with the naked eye as a dull greyish patch. With the telescope it appears oblong with a brighter ring. On the 27th the northern horn of the crescent partially intersects it, and is partially covered with the shadows of the high mountains upon the north-east side, some of which are estimated to be 16,000 or 17,000 feet high. This vast plain is believed to be a "dry flat," analagous to our deserts.

Mare Crisum is 280 miles from N. to S., 354 from E. to W., and contains 14,260 square miles, or 1-111th of the Moon's visible hemisphere. By some observers it is thought to contain a trace of green, possibly, though not probably, due to periodical vegetation. The surface is more deeply depressed than that of Mare Fœcunditatis (X) or Mare Tranquillatatis (G). Some of its boundary mountains are very steep and high. Promontorium Agarum (1) rises 11,000 feet, and the peak S.E. of Picard (4) 15,600 feet. The last-named *crater* is within Mare Crisum, as will be seen, and it is recorded by some observers that regular, white ridges, like walls, are just South of Picard.

Near the E. edge a low spot may be seen in the surrounding ridge, forming a pass, and near it are several mountains, some quite lofty. Some observers believe that they have noticed changes in these. The craters in this district seem to lack the little central hills so common in the others.

A strange story is told of an observation made on this sea by a pupil of the astronomer, Lambert; it is as follows: The night was perfectly clear, and with a common 4 feet refractor he saw four bright spots in Mare Crisum, two of which are now known. After noticing them for two hours he found, all at once, that the part of the terminator, or horn of the crescent, in M. Crisum, had a slow reciprocating motion, oscillating between the pairs of black spots in five or six minutes. The same phenomenon was observed with larger and smaller telescopes. A similar occurrence has been noticed in the case of Jupiter's satellites, during transit, and with stars when about to be occulted by the Moon. It seems to be some kind of an optical illusion which has never been satisfactorily explained.

Penn Yan, N. Y.

On Drills and Drilling.

THE attention of many professional men and others interested in mechanical operations has for a lengthened period been directed to this subject. As must be well known, there are a great many descriptions of drills now in use—some good some indifferent. The American twist-drills are now sold in large quanties, and for some purposes answer exceedingly well; but at the same time there are points to be reckoned against them. Firstly, it is very difficult to grind both edges at the same angle, and if this is not done, the result will be that the hole will not be the true size of the drill used; this will deceive a workman, and may probably spoil good work. And another objection to them is, that when the drill is about to come through the hole being bored, the quick twist causes it to worm through at such a speed that, in many cases, the drill is either broken, or the work forced up to the end of the twist, thus spoiling what might otherwise have been a smooth hole. We consider that the best description now in use is the straight fluted drill, which was originally introduced by a Mr. Martin, of Charlton; but this gentleman having for some long time ceased to make them, there arose a difficulty in procuring them. They are now, however, to be had more readily, and a set of these drills should certainly be found amongst the tools in every workshop.

With all the improvements that have from time to time been introduced in the various drills, in most factories, we have frequently noticed, that except for very large work, every workman prefers to make his own drills, and from personal experience we have found no better drills than those thus made, to do which is a simple process. For example, a drill-chuck being fitted to the lathe, with a round hole ¼ in. in diameter, and a fixing-screw; have always at hand a bar of round cast steel of the correct diameter, to fit the hole, and cut off a length as required. If the drill is to be made of a large diameter, it must be flattened out at the forge to the desired size, and then finished with a file. Most workmen, nowadays, simply forge their drills and grind them into shape; this answers every purpose for work that does not require any finish, all that is necessary is that the tool should run pretty true in the lathe and cut well. In boring a hole in thin work it becomes necessary to make it flat at the bottom. To do this a small half-round bit placed in the same chuck answers the purpose. This is essential where the hole has to be topped, as it allows of one or two more threads being made by the top. If the drill is required to be smaller in diameter than the steel from which it is made, it is a simple matter to turn down the end and then file it flat on both sides, to the same shape as the larger one previously mentioned. A great point with regard to drilling is the hardening of the drills. The old-fashioned cylinder-bit for finishing a long hole is as good as any. To

make this the circular part must be turned all over, and the cutting end filed down for about half an inch from the end. But we think the before-mentioned cylinder straight-fluted drills supersede them. In using all these drills for boring a hole between the centres of the lathe, it is a most essential thing to let the work turn round occasionally in the hand. A certain way of boring a true hole of large diameter, say ¾ to 1 inch is to fix in the chuck a well-made cylinder-bit, and carefully fix the work on the saddle of a self-acting lathe, and place on the change-wheel used for a fine finishing cut. * * * For very small work the bow drill is a most useful tool. Bows are made in many ways, and from different materials. Those for sale are of steel, with a hook at the end, over which a thin catgut is looped, with another hook near the handle, and to alter the tension a small toothed wheel with a detent is used. * * The Archimedian drill is also used for many small pieces of work. This is made from pinion-wire carefully twisted into the form of a very quick screw; and to tap the nut for it a similar short piece must be made and the end tapered off to the bottom as if were of the thread. This done a hole must be drilled in the piece of metal that is to form the nut, and the tap, as we will call it, be driven through it. This will form a corresponding screw for the long one to work in. * * * To know how such a thread is put into a piece of metal may be of service for other purposes.—*Forge and Lathe.*

Polishing and Finishing Metals.

We now come to the means adopted for finishing and polishing steel and iron. Take, for instance, a surface of steel as an example—the square stem of a drilling instrument will form a very good subject. After it is roughed out, and the work all done, it must be draw-filed, and this must be done with a superfine Lancashire file, and the lines must be kept quite straight, otherwise it will require so much emery-paper that the edges will lose the sharp angles which are the beauty of the work. Any ordinary workman can rub away with emery-paper, but in so doing he may spoil the appearance of a piece of good work, and that without knowing it. To avoid this, the smoother and better it is filed the less paper will it require. To get the beautiful finish we see on the best work, a piece of flour emery-paper, well worn, and a little oil upon it, will be found the best thing to use, and when this has been well worked, to get the high polish, a piece of wood flat upon the surface, with some fine crocus, will bring it up to this state; and if any deep scratches be there, you will at once observe them, and to remove them, in all probability, it will have to be filed all over again. Now, to avoid all this loss of time, great care must be taken that the scratches are removed before any attempt is made to polish. Having finished the work so far, many prefer to see it left straight; others, again, like to see it in some way ornamented. Now, there are several ways of doing this. First, then to cross the surface. This is done by folding a piece of emery-paper tightly round a file, but the process is not the merely pushing it across the work and making a mark, but it requires some practice to produce a good pattern, and the wrist must take a kind of circular action, and by doing this each line becomes, so to speak, connected, and makes a much better finish than a series of lines only. Another process of finishing steel is to curl all over the surface with a piece of oil-stone that will cut. This is a most difficult thing to obtain, as very few stones will cut steel to leave the bright marks necessary to give it the appearance desired. When a piece of this is once obtained it is really a prize, and if it wears away it may be inserted as far as possible into a wooden handle. To use the stone when it is once obtained is the next thing. This is done by holding it firmly in the hand and moving it about in all directions, like curling brass. There is no stated number or size of the curl, but this is quite a matter of taste, and must be left to the operator. Another way of finishing iron and steel is with the scraper, which is used with both hands, and the work must be scraped in various directions, but with regularity. Large surfaces are sometimes done in this way. Lathe-beds are at times done so, but we think this is somewhat out of character, as the fact of continually drawing the poppit-head up and down the bed produces a series of lines which look most unsightly. Regarding all this, it is all a matter of taste, and the style of finish must be left to the operator.—*Forge and Lathe.*

Practical Hints.

Rat Pie.—The Rev. J. G. Wood, the well-known English naturalist, in a lecture the other day said that there was literally nothing of which he (the lecturer) was so fond as a rat pie. This was a dish which frequently made its appearance on his table, and was enjoyed by all his family. He had several friends, too, who, as he had, had overcome their prejudice, and thoroughly enjoyed a good helping of rat pie.

Paste for Mounting Photographs.—Mix throughly 630 grains of the finest Bermuda arrowroot with 375 grains of cold water in a capsule, with a spoon or brush; then add 10½ ounces of water and 60 grains of gelatin in fine shreds.

Boil, with stirring, for five minutes, or until the liquid becomes clear, and when cold stir in well 375 grains of alcohol and five or six drops of pure carbolic acid. Keep in well-closed vessels, and before using it work up a portion with a brush in a dish.

Lark Food.—The following mixture forms a very excellent food for soft billed birds, such as larks: Hemp seed, 3 parts; Zwieback (toasted wheat bread) 2 parts; Maw-seed, 1 part; Ox-heart, 1 part.

Boil the ox-heart well in water, then cut it small, and dry it in an oven till perfectly crisp. All the ingredients must then be thoroughly mixed and ground to a course powder in a mill. This is sold by dealers, as food for mocking birds, larks, and others.

For Painting, Graining and Varnishing Pine Wood.—Boil 1 lb. of logwood in two quarts of water two hours, brush this decoction well over the box—this is mahogany color. Rosewood serve the same way, but next well streak the surface, to imitate the grain of rosewood, with the following mixture: ¼ oz. green copperas in water; apply with a hard brush or fine comb; when dry, paper gently to avoid rubbing out the color, then varnish it with brown hard varnish, using a camel hair brush. If care be taken and neatly done, it will have a good effect.

To Remove Nitrate of Silver Stains.—Dr. Kraetzer, of Leipzig, proposes, as a substitute for potassium cyanide in removing stains made by nitrate of silver, the following: Ammonium chloride, 10 grams; corrosive sublimate, 10 grams; distilled water, 100 grams. Preserve in a glass-stoppered bottle. He says that with this solution the black stains may be removed from linen, cotton, and woolen goods, without injury of the fabric. It will also remove these stains from the skin, but although it is less poisonous than the cyanide, it is a corrosive poison.

The Metric System in Coins.—It may not be generally known that we have, in the nickel five-cent piece of our coinage, a key to the tables of the linear measures and weights of the metric system. The diameter of this coin is 2 centimetres. and its weight is 5 grams. Five of them placed in a row will, of course, give the length of the decimetre; and two of them will weigh a dekagram. As the litre is a cubic decimetre, the key to the measure of length is also the key to measures of capacity. Any person, therefore, who is fortunate enough to own a five-cent nickel may be said to carry in his pocket the entire metric system of weights and measures.

Magic Polishing Cloths.—For some time past there have been sold in Europe, as polishing cloths, square pieces of calico, with which metallic articles could be polished and cleaned without the intervention of other substances. They were simply impregnated with a mixture of soap and tripoli, and tinted with coralline or rouge. For a piece of fabric 30 inches long and 4 inches wide, the following quantities are sufficient: Tripoli, 2 grams (30 grs.); castile soap, 4 grams (60 grs.); water, 20 grams (300 grs.) The soap is dissolved in the water, the tripoli added, and a little solution of coralline added to impart a rose color. The fabric is then thoroughly impregnated with the mixture and dried.

Lubricators.—The efficiency of lathes, scroll saws, sewing machines, and even watches, often depends upon the judgment and care used in selecting a lubricator, and this choice is frequently ill made. Common kerosene oil is too often injudiciously used in place of a thicker or more bland oil, because the heat produced by friction rapidly vaporizes the oil and leaves the journal dry. Crude petroleum for the same reason is fitted only for very slowly-revolving journals, such as water wheels. For very heavy machinery, or for gearing, tallow and black lead rubbed up together is the best lubricant, and is also the best for wagon and carriage axles during the hot weather. For light-running machinery sperm oil is the best; good olive oil that has not become rancid and acid, is perhaps the second best, and for winter use lard oil is excellent, but is rather too drying to be a first-class lubricant. Castor oil is better for axles in the winter, and black lead with it is a help at any time.

EXCHANGES.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Revolver, microscope, microphone, 4 magnets, skates, skate sharpener, copying pad, books, magazines, $7 worth of rosettes, and lots of other things to exchange; I will give you a better trade than anyone else can. Chas. T. Conover, Esperance, Scho. Co., N. Y.

Photographs of ten of the most influential Indians of Spotted Tail Agency, including Spotted Tail and family and four oil chromos, very beautiful, for printing press, scroll saw, or offers. Luther Emerson, Creighton, Knox Co., Neb.

"Appleton's Picturesque America," never been read or handled, value $24; "Dana's Mineralogy," $10, and coins, to exchange for a breech-loading shot gun, Winchester or Evan's rifle, or offers. D. M. Fuller, Box 115, Camden, Maine.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

One pair best steel climbing irons, handsome seven shot, 22 calibre revolver, full nickel plate, ten dollars worth of boys' papers, and magazines, for works on natural sciences or offers. W. M. Stribling, Circleville, Pickaway Co., Ohio.

Will exchange phantom leaves or fern roots (maiden hair included), for sea mosses, shells or petrifactions. E. M., New Boston, Mercer Co., Ill.

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, APRIL, 1880. No. 4.

Lessons in Magic.—X.

TRAVELLERS returning from the East bring with them such wonderful stories of the marvels performed by the Indian Conjurers, that those gentlemen are looked upon by many as real miracle-workers. There is no doubt, however, that there are many persons at home equally as clever as the copper-colored jugglers, and, in all probability, far more so.

Be this as it may, a favorite announcement among professional conjurers is "An Oriental Programme," and they have often endeavored to present similar tricks to those narrated by the newspaper "special correspondent in the East."

Among the most successful of these magicians who, "having just returned from India, where, after many years of research and travel," etc., etc., was the person who appeared in London some years ago, under the name of Colonel Stodare.

As it was rather unusual to find a Colonel in the British army in the role of a magician, he drew houses crowded with the best people of the city.

Of course he had never held a commission in the army, and was, in fact, a son of old John Henry Anderson, the Wizard of the North, but this fact was not known, and his little hall was nightly filled with an audience, amongst which was no slight sprinkling of scarred veterans, genuine generals, colonels, and what not.

One night a little knot of these officers got together, and, when the performance was over, remained in the hall, determined to have a chat with Stodare. As he was about to leave one of them addressed him:

"Good evening, Colonel."

"Good evening, sir."

"Pray, Colonel, what was your regiment?"

"I beg pardon, my regiment? Really, I do not understand you."

"Don't understand me? My question is plain enough. To what regiment were you attached? You style yourself 'Colonel,' and surely you must have had a regiment."

"O, I see now. Bless my soul, a very curious mistake that, very curious. The fact is, however, I have never been in the army. 'Colonel' is simply my Christian name, as your's may be Thomas or Richard."

The inquirer, who was a genuine "colonel," apologized, laughed at the mistake, and told it at his Club as a good joke, never suspecting that the "Christian name" was a device for drawing houses, and as much Stodare's name as mine is Hannibal.

With Stodare as a "colonel" we have nothing to; it is with his tricks only that we have to deal, and they are very clever. His was, essentially, an "Eastern programme," and introduced the "'Famous Indian Basket Trick,' and 'Miraculous Growth of Flowers,' as performed only by the Indian jugglers and Colonel Stodare."

The "Basket Trick" was really startling as the "Colonel" presented it, but is suited only for the stage. But as the late Robert Heller also exhibited it, and many of our "Young Scientists" may have seen it and feel curious to know how it is done, I shall explain it for their benefit.

A wicker basket, sufficiently large to hold a grown person, is brought on the stage, turned over and opened so that the audience may see that it is not only empty, but has a solid bottom, without traps or opening of any kind.

A young lady is then introduced, and after being blindfolded, the performer proceeds to explain what he is about to do.

"I propose, ladies and gentlemen," he says, "to place this young lady in that basket, which, as you see, stands on an open platform. After she is inside I will take a sword, which, I assure you, is without preparation of any kind, and pass it through the basket in such a way that it must inflict some wounds on the girl. She can not escape as I will fasten down the cover, and if she succeeds in getting out at the bottom you will see her, and I feel sure will let me know, otherwise it would be the means of spoiling the trick."

Whilst this explanation is being made, the young girl quietly walks off the stage, and it is not until the performer turns to assist her in getting into the basket that he discovers she is gone.

He immediately rushes off the stage, but returns in a moment leading in the girl again, and with a drawn sword in his hand. He bids her stand where she is whilst he goes down to the audience to show the sword. As he returns to the stage he remarks, "I hope you feel satisfied, ladies and gentlemen, that this is a genuine sword, but if any of you doubt it I think you will cease to do so when I begin the slaughter of this fair maiden."

At these words the girl screams and runs off the stage for a second time; the performer places the sword on a chair, goes after her again, and immediately returns, dragging her with him. Despite her struggles he forces her into the basket, and seizing the sword thrusts it into it. Screams of agony are heard, and blood is seen issuing from between the willow strands. After a while these screams become fainter and fainter, and then cease altogether.

The performer and his assistant turn over the basket and open it, so that the audience can see inside, and to the amazement of everyone it is empty. At the same moment the young lady walks up the aisle of the hall, mounts the stage, smiles, and courtesies to the bewildered audience.

Although the trick in this shape is comparatively new, the basket for it is made after a very old pattern, having been used in pantomines for many years under the technical name of a "harlequin-box." I do not know who was the inventor of this ingenious box, but am inclined to give the credit of it to the Chinese, as I have often seen the jugglers in their country use it.

The basket is made with four sides and a lid, but no bottom. The depth and width are of the same measurement. The bottom is made of wood, or rather the bottoms are, for there are two, equal in size, and joined together at one edge so as

to form an angle. When these are fitted to the wicker basket, the one marked A forms a bottom for it, whilst B fits closely to the inside of that part that faces the audience, making a sort of false side. Having been fastened in the lower front corners by large pins, that will allow it to work freely, the apparatus is complete.

When the performer wishes to show the audience the inside of the basket he turns it over. In this position they see the whole interior and one side of B, which *was* the false side, but now appears to be the bottom.

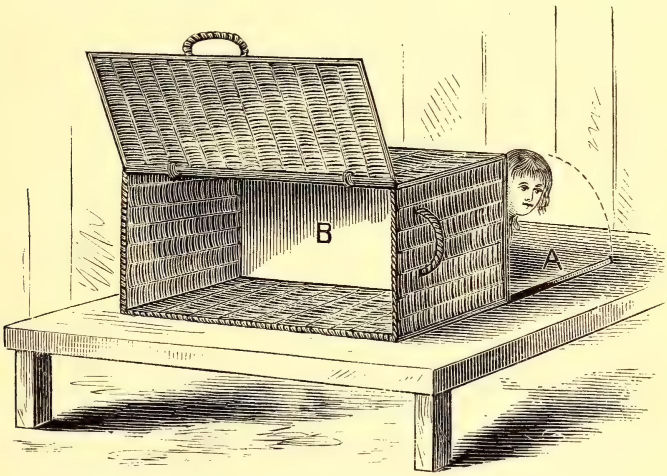
Supposing a person is in the basket and the performer wishes to show it to be empty. The man who is inside sits still and the performer turns over the basket; by this movement the person who was inside is brought *outside*, but is hidden by the basket, *behind* which he is now actually lying.

The basket being provided, there yet remains three other necessary things before the trick can be performed. The first is a stand about a foot high, of the same length as the basket and a little more than double the width. The second is a young girl of prepossessing appearance, and the third is *a second* young girl of equally prepossessing appearance, and as near like the other as possible. The features need not be the same, as the handkerchief used in blindfolding hides those.

When the first girl is brought on the stage the performer delays blindfolding her, so that the audience may get a good look at her and become familiar with her face. When she runs out she is brought back again, but when she runs out the second time the other girl is dragged on in her place, and being immediately forced into the basket the audience do not have time to notice the change.

In arranging the basket it must be placed far enough back on the stage to prevent those who are sitting at the sides from seeing behind it, or else they will discover the girl. This may be prevented in a great measure, however, by arranging chairs and stands at the ends, as if for your own convenience, for instance: at one end a stand with drapery falling to the ground may be stood to hold the sword, whilst at the other a similar stand and a small footstool may be placed as if for steps leading to the basket.

The blood which flows from between the crevices is caused by the girl who is inside squeezing a sponge filled with any good red fluid.



THE BASKET TRICK.

Drawing Lessons.—VI.

BY JOHN CLARK CENTER.

Figure Drawing.

WHERE it can be procured, a plaster cast of the human form or part of it makes the best lay figure. The materials required for drawing are a few pieces of charcoal, Nos. 1 and 2 black chalk, a leather stump, a port-crayon, and some regular crayon paper, slightly tinted, as this takes the chalk best.

The light should be allowed to fall on the sketch from the left hand. The pupil should sit with his head thrown back from his drawing as far as possible, in order to catch the proper effects of the parts sketched. A correct outline of the subject should first be drawn with the charcoal, which is easily dusted away by a very soft handkerchief: this is better than rubbing out, as friction destroys the surface of the paper.

After a correct outline is obtained, trace with the black chalk as faintly as possible, when the chalk can be dusted away with the handkerchief, which will leave a beautiful clear outline; after which he may begin the shading.

Scrape a little of the chalk as fine as possible on a paper, rub the stump amongst the powder. Taking this, rub in the shadows—these will, by proper care, be soft and beautiful, and will furnish a good ground for the finish.

Having carefully studied the different strengths of the shadows and the roundings they produce, with a fine point on his chalk let the details be put in. He should patch over all the shading with this fine point. This, when done with proper care and skill, gives a very beautiful effect. In shading, the pupil must observe that there are two kinds of shadows; one is called the shadow of incidence, the other the shadow of projection. The first is always soft, having no defined edge, but softening imperceptibly into the light. The shadow of projection is always defined, having a sharp, decided edge. Avoid all hardness of edge, as the deepest shadows are always nearest the highest lights. If any mistakes are to be corrected or greater softness be required in any of the parts, a little stale bread will remove the chalk, and by careful application a very beautiful effect can be produced in subduing and blending the different shadows.

This treatment of chalk as a medium for drawing is that used by schools of art, and can be studied in the crayon portraits of your friends, and other works of art of a similar character.

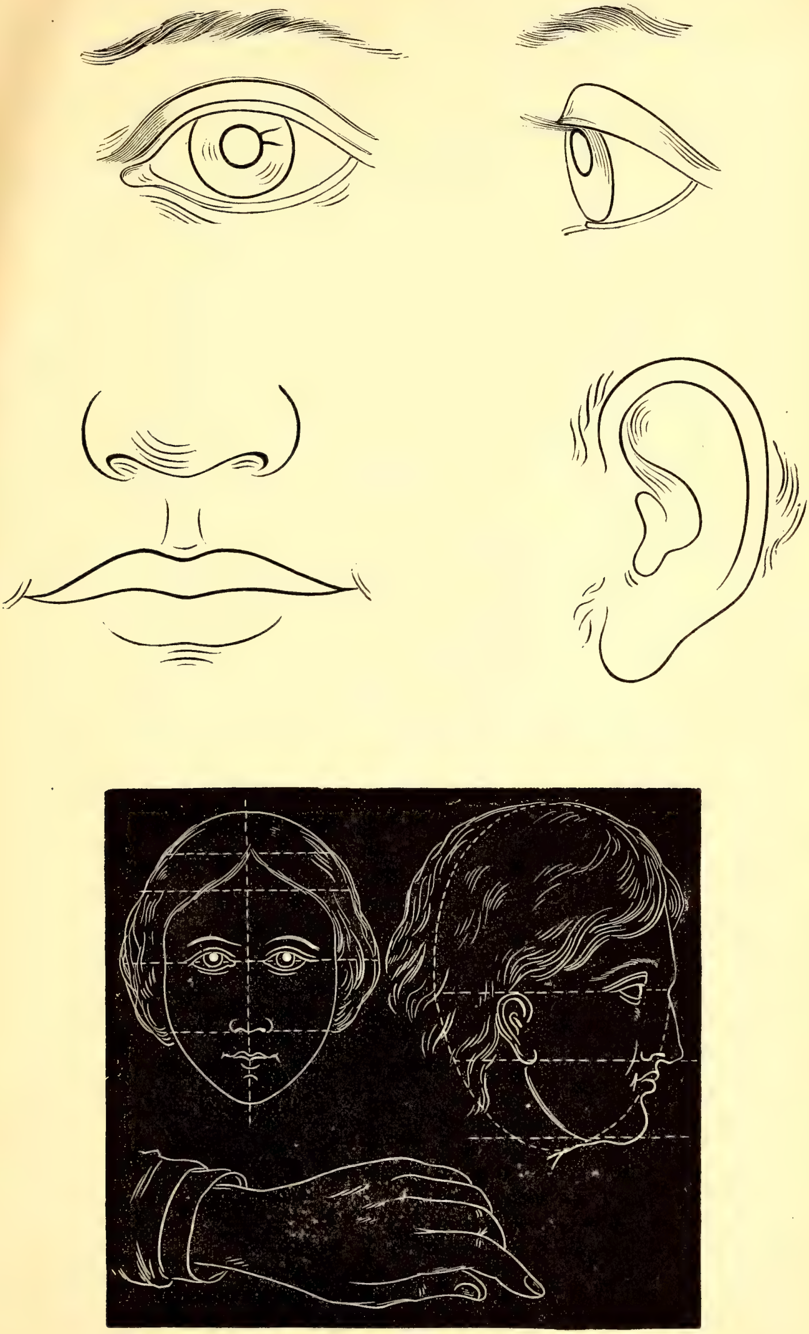
We would recommend those who have models, of whatever kind, to practice this method of shadowing in drawing them; and when they attempt to draw the human "head divine," or other parts of the body attached to "that head," each part of which is a study in itself, or the clothing or draperies which may cover or surround it, demands will be made on manipulative ability for the treatment of each, and the textures will call for experiments until the desired goal of perfection is reached and the "prize is won."

In closing these lessons we will present in the accompanying illustrations the proportions which different parts of the human frame bear to each other, according to the acknowledged standard of beauty, as derived from measurements from the antique. These will be of great assistance in drawing from casts. We must not suppose that beauty is so much dependent on these rules as upon correctness. There are many styles of beauty, the different styles often resulting from the slightest deviation in some point or other from established proportions.

The mouth, in width, is equal to the length of one eye and a half, in profile it is exactly the same height, but only half this width; the upper lip projects less than the lower one.

The nose, in width, is equal to one eye, and in height to two from the eyebrows.

The eye is composed of the ball, the sight, the lachrymal point (which is the point nearest the nose), the upper and lower eyelids, and the eyebrow. The ball, when seen in front, is an exact circle, with the sight in the centre. The height is equal to half the length, and the eyebrow is situated above the eyelid about one-third the length of the eye. In profile it is the same height, half the length as



ELEMENTS OF FIGURE DRAWING.

seen in front. The eyeball forms an ellipse, with the sight always in the centre.

The ear, in width, is equal to one eye, in length to two. The hand is the same length as the face, in width one-half. The foot, in profile, is nine eyes in length and three in height.

The proportionate height of a man is ten faces; and extending the arms horizontally their full length the same proportion is obtained.

These measurements are only suggestive of some of the more important proportions of the human body which the student of art and truth must master.

Home-Made Telescopes and Microscopes.—IV.

THE POWDERS EMPLOYED FOR GRINDING AND POLISHING GLASS.

SUCCESS in producing well-finished lenses will depend a good deal upon the excellence of the grinding and polishing powders used. In regard to this point Mr. Wenham gives the following directions:

"For lenses, emery is almost invariably employed for rough grinding and smoothing. For the latter operation it must be washed to various degrees of fineness, as it is seldom sold in this state; the sizes in commerce are merely sifted. Emery differs much in hardness and quality, according to the locality from which the ore is obtained. If it is full of small reddish particles, of a dull slaty appearance, it is soft, and deficient in the grinding property. The Guernsey emery is of this character, and very inferior to the Naxos, the particles of which have a steely appearance of uniform color; but this latter is difficult to obtain, as it is monopolised by some of the large plate-glass manufacturers. Three or four sizes are sufficient for the glass worker for roughing down and fine grinding; but for smoothing, washed emery of several degrees of fineness are required. A portion of the flour of emery of commerce is placed in a bowl, or a common wash-hand basin, and well stirred up. At the end of ten seconds the water is poured into another bowl; this is repeated several times, till no more can be withheld from the original quantity. This washed quantity is again separated into several other degrees of fineness, as at the end of one minute, five, twenty, and sixty minutes; but, after one hour, a very small quantity is obtained from one pound of the flour of commerce. This being of value for the perfection of the final smoothing, or obtaining a semi-polish on the metal lap or mould itself, I have preferred procuring it from the "optician's mud," or refuse of the previous grinding operations. Taken in an unprepared state, this contains a large percentage of impurities, consisting of ground glass and metal particles from the laps; it is, therefore, necessary to remove them. The first by boiling the mud with caustic potash, and after washing away all trace of the alkali, finally treating with dilute sulphuric acid. The finest portion only of one hour's suspension may then be separated and in a satisfactory quantity.

"The polishing powders used by the workers of minute lenses, are putty-powder, or oxide of tin, and crocus, or peroxide of iron. The first may be obtained sufficiently good without any difficulty; but after many trials, both by roasting the alkaline precipitate from sulphate of iron, and also carefully washing the crocus of commerce, I have given the preference to jeweller's rouge. In this form it is far too soft for glass polishing; it must, therefore, be heated in an iron pot, and dilligently stirred till the mass acquires a purple color; it is then of the requisite degree of hardness. Both this and the putty-powder must be washed, to separate gritty particles; about five minutes will be sufficient. After obtaining all that can be suspended in this time, the residue may be levigated on an iron plate, with a soft iron spatula, and the washing continued at pleasure; but the result of all the washings is sure to contain some gritty particles, which must be separated by repeated washings till nothing whatever will settle at the end of five minutes. Two sizes of crocus only are needed; the last is obtained from the washed mass after one hour's suspension, and is very small in quantity but of much

value for obtaining the finest polish on prism work, either in glass or calc spar. The ordinary washed crocus, used alone, I have found too keen, and apt to cling to and raise streaks on the polishing laps; I, therefore, always mix it with an equal part of the putty-powder, which quite remedies the evil; an uniform mixture is best obtained by stirring them together with water."

Skin Preserving.—II.

(Continued.)

THE skin is now ready for making up. Of course some preservative composition is a desideratum; and the best is the time-honored arsenical soap. That which I have used, and which answers perfectly, is made of one ounce of white arsenic to four ounces of yellow soap. The soap is first shredded into a pot; and melted by being stood in hot water; and the arsenic stirred in gradually, then allowed to cool; covered, and a poison label affixed. But in case there are nothing but the ordinary household stores available, skins will keep very well, and for an indefinite time if the moth be kept from them, by curing with equal parts of alum and salt. This is rubbed into the skin extended on a board, and allowed to dry; after which the superfluous crystals are brushed away. This, however, has disadvantages, owing to the hard coating given to the skin, but for curing skins not meant for further stuffing than sufficient to retain their form, is quite satisfactory.

We now come to the final making up; and here the materials required are again simple; the preservative, tow, a needle and cotton, stout thread, and the scissors. The first step is to examine the skin, and remove any superfluous fat which may have been left attached; and to see that no portions of muscle remain on the broken ends of the limb bones; in doing which the preservative is well rubbed over the interior of the pouch formed by the skin of the legs and wings. Before returning the ends of the bones into the sheath, a shred of tow is wrapped round the end of the bone, and then formed into a pad as nearly as possible the size of the removed portion which still remains attached to the body, and the limbs will require no further treatment.

The whole of the skull, inside and out, is now treated with preservative, and the orbits filled with tow to as nearly as possible the natural amount of fulness given by the eyes when in their place—and the back of the skull is replaced by a ball of tow rolled up tightly, so as to fit the interior and give the requisite roundness lost by the removal of the hinder third in cleaning. The head is then gently returned through the "glove finger" formed by the neck, and any sinking about the eyes rectified by inserting more scraps of tow through the eyelids. The neck is then filled by gently passing up shreds of tow by means of a stick, taking care not to overfill it, or leave lumps of tow evident by their undue protrusion.

It is better, at this stage, to bring together any small gaps in the skin caused by shot or accident during skinning, by means of the needle and cotton, avoiding the rumpling of plumage, which would be caused by including the root-ends of feathers in a stitch.

There only remains now to pad the body to prevent undue shrinking during the drying stage. This may be done either by merely filling up with loose tow, folding the skin over and allowing it to dry in position, or by making a fresh body of tow to replace the natural one as nearly as possible; and this latter method is, I think, the better.

Taking the body, which has been kept as the model, a lump of tow is rolled into a compact ball, rather larger than the required size, and of the same proportions. The strong thread is then wound around it tightly, reducing it to the right size, and, with a little management, giving a pretty correct model of the contour of the breast, etc. If anything, when completed, the tow body should be smaller than the natural one, to allow for the unavoidable shrinking of the drying skin. It is then placed in position, and the skin of the breast brought together evenly across it by a few stitches in the edges of the bare streak along which the first cut was made. Holding the skin by the beak, the feathers are carefully smoothed down, and returned

to their natural positions. There will be no difficulty in the pose of the wings, which, unless stretched, will fall perfectly naturally into their places. The skin should be laid carefully on its back on a flat surface, in the same position as when held by the beak, securing the wings, if necessary, by a thread passing round the body, and left untouched till dry, which will take a longer or shorter period, according to the size of the specimen, and the state of the weather. Occasionally during drying there will be a tendency of some few feathers to become prominent, owing to contraction; if they are few, they may be removed when the skin is dry; but in the case of a tuft of plumage, they must be kept down, either by a weight or by a strip of paper crossing them and pinned through the skin to the tow body; but, unless the body is overstuffed, there should be no difficulty as to smoothness of feathers. Perhaps the thick tuft covering the shoulders is most prone to rebel, and I have often found it useful to surround the wings with a broad strip of paper, secured by one pin through the breast, instead of the thread.—*Science Gossip.*

To be Continued.

How Plants Breathe.

IN a former article we described the manner in which insects breathe, and gave a cut of the spiracles or openings through which the circulating system of the insect communicates with the air. We now give a description of the way in which plants breathe.

The breathing of plants, if it may be so called, is, however, just the opposite of the breathing of animals. The animal requires oxygen, which burns up the used-up tissues of the body and makes heat to keep that body warm. The product of this combustion, carbonic acid, is then thrown off, and this carbonic acid, which would be poison to animals if again breathed, is the breath of life to plants, for they decompose it, use the carbon for the purpose of building up their tissues, and give off the oxygen, which again becomes the breath of animals. In this way plants and animals form a mutual balance, each supplying what the other needs, and consuming that which the other throws off.

If we take the fruit leaves of almost any plant, and strip off a little of the cuticle or thin outer skin, we will find that under the microscope it presents an appearance somewhat like Fig. 1. All over the surface will be seen the stomata or openings, five of which are shown in the engraving.

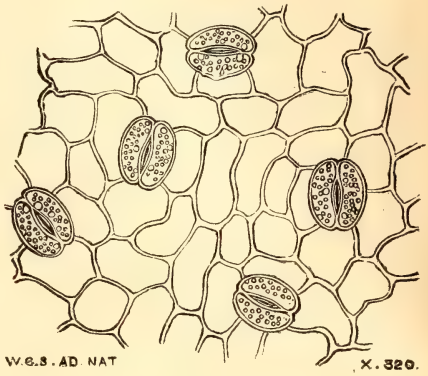


Fig. 1.

In some plants, such as the *Hydrangea*, there are 160,000 of these openings to every square inch. In other plants there are fewer; thus the *Yucca* has 40,000, and the *Iris Germanica* 12,000. The best way to procure the cuticle for examination is to take a very sharp knife, cut the cuticle across, raising it a little at the same time, and then, grasping it between the thumb and the edge of the knife, strip it off by gently pulling it. There is a knack about this which is more easily shown than described, but a very few trials will enable the young microscopist to succeed, and then he will have a wide range of subjects from which he may select beautiful objects for his cabinet. In a future article we will explain the best methods of mounting them.

In Figure 1 the stomata are shown as they appear when seen from above. The way in which they open into the interior of the leaf can only be shown by a cross-section of the leaf, such as is shown in Fig. 2. Such a section is easily obtained by fastening a leaf between two pieces of

carrot, and shaving off very thin slices with a razor. The razor must be sharp and should be kept well moistened with a little water, to which a small quantity of alcohol has been added. The thin slices, or sections, as they are called, are floated off into a basin of water, whence they are lifted out, placed on a slide, covered with

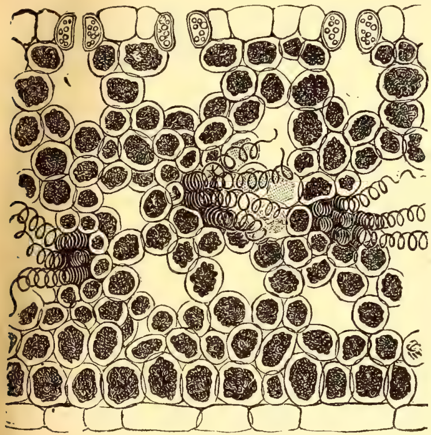

Fig. 2.

thin glass and examined under the microscope. The openings from the interior of the leaf to the outer air through the stomata will then be readily seen.

In cutting these sections the leaf and its supporting carrot may be held in the hand, but this requires a good deal of dexterity. The easiest way is to fix the whole in a section cutter as it is called. Section cutters are kept for sale by most dealers in microscopes, but a home-made one, which will do very good work, is easily made, and some day we will tell our readers how to make one.

Astronomy for Amateurs.

BY BERLIN H. WRIGHT.

Correspondence.

A Cheap Audiphone.

Ed. Young Scientist—For the small sum of ten cents, I can make what I call on "audifan," that will give as good satisfaction as any audiphone invented. I take a common Japanese fan, one with reed handle and braces entire, cut off about one half inch from the top edge, adjust thereto a small strip of tin, binding four or five inches in length and one quarter inch in width when doubled, and clinch the same for a mouthpiece. I then give the whole fan one coat of shellac and lamp-black, using enough black to overcome in part the gloss of the shellac. If one end of a small strip of curved brass wire be inserted just over the string that gives tension to the curved wooden brace, so as to rest against it, and the other end is clinched between the edges of the metal binding, the fan will assume the proper position and always be ready for use. The fan should be painted and allowed to dry thoroughly before the curved brass is adjusted. The fan can be used without the brass brace, if a narrow strip of silk be pasted down the centre of the fan to protect the paper.

L. B. De Veau, New York.

Paste Eels.

Ed. Young Scientist—The paste came safely to hand, and by following your directions, I soon had a large supply, enough for all my friends, but, although it was easy to see the eels by transmitted light, I found it very difficult to get good results with black-ground illumination, because the paste with which they were mixed reflected the light in all directions, and the effect was entirely destroyed. The question then was, how to get the eels free from the paste in which they lived? The following simple manner of solving this problem may be of interest to your readers.

I placed some paste (about a tablespoonful) in the bottom of a tea-cup, and placed it in a warm place. The eels bred and grew rapidly, so that in forty-eight hours it was a seething mass of life. At the same time the paste dried up and became firm. As soon as the paste was so solid that it would not readily mix with water, I placed a piece of stiff paper, about three-quarters of an inch in diameter, on its surface, and on this paper I poured about half a teaspoonful of water. The object of the paper was to prevent the stream of water from disturbing the paste. After the water had stood about half a minute to a minute on the paste, I removed a drop by means of a dipping tube, and deposited it on a clean slide. It was full of eels. and almost quite free from paste, so that when illuminated by very oblique rays, the little animals appeared like luminous serpents moving about in a dark sea. When the paste is allowed to become partially dry, and water is laid gently on its surface, the eels pass at once from the paste to the water and the latter is literally filled with them.

Annealing Steel in Boiling Water.

Amateur mechanics who work steel either in the vice or the lathe, are often annoyed by the difficulty of softening certain pieces. Some specimens of steel, when heated to a low red heat and slowly cooled in ashes, become quite soft; other pieces wholly resist this treatment, and although they can be cut and filed, they do not come to that fine softness, which makes a piece of well-annealed steel so pleasant to work. Other pieces again become "pinney," as it is called, that is, full of spots which are quite hard, while the rest of the metal is quite soft. The observations of Prof. W. Mattieu Williams will prove interesting to those who have been troubled in this way. He says: "I will narrate some curious experiments that I commenced when in Sheffield, but have not satisfactorily completed. They were made at the suggestion of Mr. William Bragge, then a managing director of Sir John Brown's works. He had learned that the steel wire strings of piano-fortes are annealed by what appears a very anomalous process—viz., by making the wire red-hot and then plunging it into boiling water. Ordinary experience would suggest that this must harden the steel in some degree, but I tried it upon many samples of steel—mild Bessemer steel, sheer steel of different qualities, and the hardest old-fashioned Sheffield 'pot-steel'—and found that in every case, when the operation was properly performed, the steel was remarkably annealed. I compared samples cut from the same bar—one heated and slowly cooled by burying in ashes under a furnace grate, the other by immersion in boiling water—and found that when subjected to bending tests those which had been cooled in the boiling water would bear a more severe degree of flexure without cracking than the pieces which had been more slowly cooled in the ashes. They were not so soft, as tested by the touch of the file, but unquestionably tougher and more reliable when subjected while cold to violent bending blows of a hammer. It was more effectual than any device of 'oil toughening' or slow cooling I have had opportunities of testing. Certain precautions are necessary. In the first place, the water should be quite at the boiling

point and the steel at a bright red heat; and secondly, the steel should be fairly surrounded by the water. These conditions being fulfilled, the steel remains red-hot under water for some time. It is evidently surrounded by a film of vapor and is not in actual contact with the water, which assumes the so-called "spheroidal state," continuing in this condition until the metal has cooled considerably. I suspect that the toughening is due to the uniformity of cooling thus effected. I commend this method of annealing or toughening to the attention of manufacturers engaged in the production of all kinds of steel that is to be used for purposes where tenacity rather than hardness is demanded."

How to Extract a Fish-Hook.

THE season for fishing is at hand, and while this is one of the sports in which but few accidents occur, it occasionally happens that by an unlucky movement, a hook gets buried in the flesh of the young angler, or of his companions instead of in the fish. In such cases, it is well to know how to get it out, for if allowed to remain, or if awkwardly handled, such a wound may prove an ugly thing. In proof of this, we cut the following account from the columns of a local journal: "Some eight years ago, a lad of thirteen, the son of a prominent citizen, while fishing from one of the wharves, caught a fish-hook in the fore-finger of the right hand, near the roots of the nail, drawing it into the bend of the hook. His father saw at once that the only thing to be done was to open the finger on a line with the hook and take it out, but preferred to call in their family physician to do it. After looking at it for a moment, the doctor, by a sudden twist, wrenched the hook from the finger, minus the bard and point. The parents were justly indignant at such treatment, and insisted that the hook was not all removed, while the boy came near fainting from extreme anguish. The doctor, however, insisted that no inconvenience would result, and dressed the finger in some simple and safe manner, and in due time the wound healed. But the finger and arm troubled him for a long time. After a year or two the lad's health had so far failed as to become a subject of serious alarm to his friends, he being subject to frequent and alarming fainting fits, and other spasmodic affections or symptoms. The state of affairs continued for years, with more or less intensity, until a year or two ago, when the boy's health became nearly or quite restored. The other day the young man, while dressing himself, tore a pimple from his left shoulder, and on examining it, he drew from the flesh the point of the hook which seven years before was imbedded in a a finger on the opposite side of his body."

The danger with most fish-hooks is that the surface and barb are smeared with putrid animal matter, either from the bait, or from the fish that have been caught. When, therefore, an old hook has been imbedded in the flesh, it ought to be cut out with a clean cut, made with a sharp knife so that the wound may be thoroughly washed out. If the hook should be new and used with artificial fly or spoon, take a sharp knife and cut off the thread, etc., with which the hook is attached to the line, and if necessary break off any eye or enlargement that may exist. Clean the shank of the hook thoroughly, and then run the point through the flesh and out.

Curious Experiment on Light and Heat.

IF a piece of wood be placed in a decanter of water, and the focus of a large burning glass be thrown upon it, the wood will be completely charred, though the sides of the decanter through which the rays pass will not be cracked, nor in any way affected, nor the water perceptibly warmed. If the wood be taken out, and the rays be thrown on the water, neither the vessel nor its contents will be in the least affected; but if a piece of metal be put into the water, it soon becomes too hot to be touched, and the water will presently boil. Though pure water alone, contained in a transparent vessel, cannot be heated, yet, if by a little ink it be made of a dark color, or the vessel itself be blackened, the effect speedily takes place.

Practical Hints.

Straightening Hardened Steel.—In hardening and tempering tools they sometimes spring, to the great annoyance of the workmen, and not seldom the tool is reheated and rehardened. In most cases this may be avoided. To straighten a piece of steel already heated and tempered, heat it lightly not enough to draw the temper, and it may be straightened by blows from a hammer, if the character of the tool will admit of such treatment, or, as in case of a tap, it may be straightened by a heavy mallet on a hard wood block. Although the steel when cold would break like glass with this treatment, when slightly warmed it will yield to moderately heavy blows uninjured.

When Trout May be Caught. –The *Sea World*, a sprightly little paper devoted to the fish interests, published at New Haven, Conn., gives the following information regarding the laws of different States in respect to trout fishing.

California, April 1 to November 1.

Connecticut, April 1 to July 1.

Iowa, February 1 to November 1.
Maine, May 1 to October 1.
Massachusetts, April 1 to October 1.
Michigan, May 1 to September 1.
Minnesota, April 1 to October 1.
New Hampshire, May 1 to October 1.
New Jersey, March 1 to October 1.
New York, April 1 to September 1.
North Carolina, January 1 to October 15.
Pennsylvania, April 1 to August 1.
Province of Ontario, Canada, May 1 to September 15.
Province of Quebec, Canada, February 1 to October 1.
Rhode Island, March 1 to August 15.
Vermont, May 1 to September 1.
Virginia, April 1 to September 15.
Wisconsin, April 15 to September 15.

EXCHANGES.

Wanted, coins, minerals, and type; send lists of what you have and what is wanted in exchange. A. Campbell, Derrick City, McKean Co., Pa.

An Excelsior Printing Press, with equipments, comparatively new, cost over $47, for double barrel breech-loading shot gun, with reloading tools and shells. William A. Hervey, Box 134, Taunton, Mass.

To exchange, 400 stamps, all different, in a stamp album, for a small printing press with type, etc. Arthur D. McGerald, 106 Bird Ave., Buffalo, New York.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Revolver, microscope, microphone, 4 magnets, skates, skate sharpener, copying pad, books, magazines, $7 worth of rosettes, and lots of other things to exchange; I will give you a better trade than anyone else can. Chas. T. Conover, Esperance, Scho. Co., N. Y.

Photographs of ten of the most influential Indians of Spotted Tail Agency, including Spotted Tail and family and four oil chromos, very beautiful, for printing press, scroll saw, or offers. Luther Emerson, Creighton, Knox Co., Neb.

"Appleton's Picturesque America," never been read or handled, value $24; "Dana's Mineralogy," $10, and coins, to exchange for a breech-loading shot gun, Winchester or Evan's rifle, or offers. D. M. Fuller, Box 115, Camden, Maine.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

One pair best steel climbing irons, handsome seven shot, 22 calibre revolver, full nickel plate, ten dollars worth of boys' papers, and magazines, for works on natural sciences or offers. W. M. Stribling, Circleville, Pickaway Co., Ohio.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho,

Will exchange phantom leaves or fern roots (maiden hair included), for sea mosses, shells or petrifactions. E. M., New Boston, Mercer Co., Ill.

Wanted, a cornet; must be in excellent order, state what is wanted in exchange. James B. Athearn, New Bedford, Mass.

Wanted, Archæological relics and fossils, for butterflies, beetles, spiders, etc. Correspondence invited. A. W. Baily, Box 195, Pottstown, Penn.

Telegraph instruments with 400 feet of wire and battery, it cost $12; will exchange for scroll saw, or offers. F. Cushing, Wattsburg, Erie Co., Penn.

An improved camera lucida for drawing, etc.; also, a printing press, chase 2½ x 3½, for offers. L. De Veau, 87 E. 10th St., New York.

What offers for a magnificent black walnut mineral cabinet, 5 ft. x 4 ft., desk form, and double, has 4 glass doors, 12 drawers, veneered panels, with drop handles, massive carved legs, and is lined in blue, cost $80 cash. W. L. Farnum, Owosso, Mich.

Postage stamps, spectograph, drawing cards in case, sketch blocks, size 12x20 and 9x12 in., one book, "No Alternative," for minerals, coins, birds eggs, Indian relics or offers. Frank F. Fletcher, St. Johnsbury, Vt.

To exchange: well-mounted slides of hair and fur, for other well-mounted slides of same, lists exchanged. Address, W. Hoskins, 208 S. Halstead St., Chicago, Ill.

Rare insects, minerals, and shells, in exchange for scientific books. P. W. Lee, 310 Marlborough St., Boston, Mass.

A set of carving tools worth 75c.; card stamp and type worth $3.00. State offers, magic lantern preferred. Address Frank H. Libby, Saco, Maine.

A first class sewing machine will be exchanged for books or offers. Address, Lock Box, 22 Schoharie, New York.

Gaskel's compendium, and Virgil's works translated by Dryden. State offers. G. Osgood, Jr., Abington, Mass.

Cocoons of attacus cecropia or mounted specimens of Lepidoptera to exchange for the following cocoons: "A. Luna," "A. Prometheus," "Saturnia Io," a "Ceratomia quadricornus." R. Perry, 50 E. Washington St., Indianapolis, Ind.

Wanted, in exchange for one vol. of "The Boys of New York," or the "Young American," a two line card printer with type and everything complete. Address, W. H. Pretty, Bellville, Ont., Canada.

Wanted, to exchange, Lake Superior copper specimens for type. T. J. Prince, Houghton, Mich.

For exchange, a small lathe, (foot power), 2 sewing machines, 1 Wheeler & Wilson, 1 Singer, medium, in good order, but little used: wanted cabinet makers tools, tent, or scroll saw. R. P. Wakeman, Southport, Conn.

Wanted, a printing press and type; state what is wanted in exchange; "Official" preferred. A. Campbell, Derrick City, McKean Co., Pa.

Thos. D. Adams, Franklin, Pa., will exchange a $25 lawn mower, $60 coffee roaster, type, cards and books, $60; poultry journals, $10; 2 cocker spaniels, $30; 1 pair do., $80, and 1 pair $60; for key check outfit, improved model press, or offers.

To exchange, 270 foreign stamps, many new and all different, and a boy's printing press, size, inside chase, 3x4¾ inches, worth $9, for books, microscope, or offers. Henry J. Bott, La Fargeville, Jefferson Co., N. Y.

A Lozo-pendulum board (lined with genuine billiard cloth), consisting of ring toss, bagatelle, pockets, and ten pin, to exchange for parlor magic, aboriginal relics, or offers. T. C. Gard, Frankfort, Indiana.

VOL. III. NEW YORK, MAY, 1880. No. 5.

How the Spider Lifted the Mouse.

ONE of the most interesting books on natural history is a work on "Insect Architecture," by Rennie. But if the architecture of insect homes is wonderful, the engineering displayed by these creatures is equally marvellous. Long before man had thought of the saw, the saw-fly had used the same tool, made after the same fashion, and used in the same way for the purpose of slitting the branches of trees so that she might have a secure place in which to deposit her eggs. The carpenter bee, with only the tools which nature has given her, cuts a round hole, the full diameter of her body, through thick boards, and so makes a tunnel by which she can reach a safe reteat in which to rear her young. The tumble-bug, without derricks or machinery, rolls over large masses of dirt many times her own weight, and the sexton beetle will, in a few hours, bury beneath the ground the carcass of a comparatively large animal. All these feats require a degree of instinct which in a reasoning creature would be called engineering skill, and yet none of them are as wonderful as the feats performed by the spider. This extraordinary little animal has the faculty of propelling her threads directly against the wind, and by means of her slender cords she can haul up and suspend bodies which are many times her own weight. A paragraph has been going the rounds of the papers that a spider recently suspended an unfortunate mouse—raising it up from the ground and leaving it to perish miserably between heaven and earth. Would-be philosophers have made great fun of this statement, and ridiculed it unmercifully. We know not how true it is, but we do know that it *may be* true. Some years ago, in the village of Havana, in the centre of this State, a spider entangled a milk-snake in her threads and raised it some distance from the ground, and this too in spite of the struggles of the animal, which was alive. No doubt some wiseacres will deny the possibility

of such a thing, and intimate that it has its foundation only in the mendacity of the relator, but it is true nevertheless.

By what process of engineering does the comparatively small and feeble insect succeed in overcoming and lifting up, by mechanical means, the mouse or snake? The solution is easy enough if we only give the question a little thought.

The spider is furnished with one of the most efficient mechanical powers known to engineers, viz.: a strong, elastic thread. That the thread is strong is well known. Indeed there are few substances which will support a greater strain than the silk of the silkworm or the spider, careful experiment showing that for equal sizes the strength of these fibres exceeds that of common iron! But notwithstanding its strength, the spider's thread alone would be useless as a mechanical power if it were not for its elasticity. The spider has no blocks or pulleys, and therefore it cannot cause the thread to divide up and run in different directions, but the elasticity of the thread more than makes up for this, and renders possible the lifting of an animal much heavier than a mouse or a snake. This may require a little explanation.

Let us suppose a child who can lift a six pound weight one foot, and do this forty times a minute. Furnish him with 350 rubber bands, each capable of pulling six pounds through one foot when stretched. Let these bands be attached to a wooden platform on which stand a pair of horses weighing 2,100 lbs., or rather more than a ton. If now the child will go to work and stretch these rubber bands, singly, hooking each one up as it is stretched, in just ten minutes he will have raised the pair of horses one foot! In other words, the elasticity of the rubber bands enables the child to divide the weight of the horses into 350 pieces of six pounds each, and at the rate of a little less than one per second he lifts these separate pieces one foot!

Each spider's thread acts like the elastic rubber bands. Let us suppose that the mouse weighed half an ounce and that each thread is capable of supporting a grain and a half. The spider would have to connect the mouse with the point from which it was to be suspended with 150 threads, and if the little quadruped was once swung off his feet he would be powerless. By pulling successively on each thread and shortening it a little, the mouse or snake might be raised to any height within the capacity of the building or structure in which the work was done. So that to those who have ridiculed the story we may justly say: "There are more things in heaven and earth than are dreamed of in *your* philosophy."

What object the spider could have had in this work we are unable to see. It may have been a dread of the harm which the mouse or snake might work; it may have been the hope that the decaying carcasses would attract flies which would furnish food for the engineer. With this, however, we are not so much concerned. Our object has been to explain and render credible some extraordinay feats of insect engineering.

Bird Houses.

A NEATLY-MADE bird house is not only a source of pleasure and profit, from the fact that it attracts the great friends of the gardener and keeps them about the place, but it is also an ornament, if properly located and constructed in harmony with its surroundings. Last year we gave several figures of bird houses with directions for making them, and we now give another which has a different arrangement and appearance, though chiefly constructed out of waste materials. The house shown in the accompanying engraving consists of four nine inch flower pots, resting on a base board shaped as we have figured it in the engraving. Through the centre of the base board there is inserted a pole, which passes through far enough to allow for the height of the flower pots and the thatched roof.

The flower pots are placed around the pole, which is nailed to the base board. A hole is cut into the side of each pot for an entrance for the birds. The pots can be ornamented to suit the fancy, either with plaster of Paris, burrs and lichens, or they may be painted of some sombre color. The second story of the house is

formed into compartments by nailing partitions to the pole, so that when the thatched roof is applied, four compartments are established. For making the thatched roof, the straw is first bound to the top of the pole with wire; it is then brought down to the tops of the pots, and extends over so as to form a continuous eave. The straw composing the thatched roof must be firmly sewed together, either with wire or strong twine. When the roof is completed holes are cut into it for entrance to the compartments. Here again the straw must be carefully bound together, or it will fray apart.

A. W. Roberts.

HOME-MADE BIRD HOUSE.

Skin Preserving.—III.

(Concluded.)

QUADRUPEDS are prepared, when small, in precisely the same way; but owing to the shrinking of lips, etc., they are never satisfactory; and if required for stuffing, had better be packed off at once, unless they can be finished on the spot. Still, skins are ornamental, and I may conclude by one or two remarks as to preparing them for other purposes than stuffing, e.g., mats.

For this purpose I have found nothing better than the alum and salt already mentioned. Taking the animal, the body is laid on its back, a cut made through the

skin from chin to tail, and two transverse cuts across the first to a short distance along the inner side of the legs, as far down towards the feet as the length of skin to be removed from the limb requires. In case the head is not to be retained, a cut is made from the bridge of the nose, past the angles of the jaws, to the first cut below the chin on each side, so that when the whole skin is removed, the included portion remains attached to the jaws, while the eyelids and ears are removed with the rest of the skin, the bone is drawn from the tail. The next step is to tack the skin, with the hair downwards, to a bqard; stretching it only just sufficiently to render it quite flat, and putting the tacks as near the edge as possible. Any adherent fat is then removed with a blunt knife, and the whole surface slightly scraped. It is then thoroughly rubbed with equal parts of alum and salt, and set aside for two days to dry. A second curing, and in two more days a third, are required, and the skin should be by the end of a week nearly dry; but it will be perfectly stiff and hard.

Taking the blunt knife, the best form of which is the ordinary round-pointed table knife, the skin is thoroughly scraped, and the scraping continued till the hard surface is removed, and the skin is as pliant as washleather. In a day or two more a second, very rarely a third, scraping may be necessary, and the skin is then fit for use, and perfectly sweet.

There is one beautiful skin which deserves special mention in connection with this method of curing—the mole's. The best way to preserve it is by making a circular incision round the chest, as close to the "hands" as possible, and then turning the skin inside out over the body; so that as much as possible of the skin is left untouched. The method of drying is to fit the pocket thus obtained over a wooden cylinder, about twelve inches in length, and of the requisite diameter, and proceeding in the usual way. The hind feet may be cut off close to the skin, as they leave no appreciable hole.

So far I have given an outline which may be useful to some of the readers of this journal. I do not lay claim to much originality in method, but I have tried to put myself in the place of a beginner, in describing the ins and outs of the simple process which puzzled myself at first, and to give some idea of the way in which I have learnt to overcome the difficulties I have met with. If I have succeeded, it may be that a rare specimen may be saved from loss, and I am content. Who knows whether, if some Dutchman had only known how to make up a skin, there might not be a stuffed specimen yet existing of the Dodo!—*Charles D. Whistler in Science Gossip.*

Home-Made Telescopes and Microscopes.—V.

ON THE PRODUCTION OF FLAT SURFACES IN GLASS.

THE most important tools required for the work are three circular cast-iron laps, about 6 inches in diameter, having a screwed boss at the back, similar to the face-chuck of a lathe. These must be first turned flat on their faces, and then scraped to a true surface, either from a standard planometer, as practiced by engineers, or else the three may be scraped together till no error can be detected by their interchange. It would, perhaps, be out of place to give the details of this operation, which is described in most elementary works on mechanism. These planes, as left by the scraper, are not sufficiently smooth for the purpose required; they must, therefore, be ground together. One of the plates is screwed down on a stud fixed in the bench or vice, and a wooden knob is fixed into the other to serve as a handle; they are then rubbed together with fine emery and water, frequently interchanging the plates. It is a very difficult matter to bring these plates to an exact plane by grinding alone, and to keep them so during their continued employment. The test of their truth is, that after they are all wiped clean and dry, and rubbed together, the three should present a mottled appearance, uniformly covering the whole of their surfaces. One cause of error is a natural tendency of the grinding-powder to collect unequally between them. This may be somewhat corrected

by frequently wiping it away from the places known to be hollow; and the grinding together should be performed with as little powder as possible at a time, and the strokes so managed as to abrade the high parts only. Practical experience is the best guide for this; and a clever workman will soon learn in what way and direction to work his blocks of glass, etc., on the laps, with very little injury to their plane figure, or even for the purpose of correcting it. In consideration of the extreme accuracy required in the prisms for spectroscopes and other purposes, no pains should be spared in maintaining the perfection of these laps.

If a number of discs of glass intended for small lenses are required to be ground and polished to a flat plane, they must be cemented to a "block;" this is frequently merely a piece of wood turned with a convenient knob at the back for handling; others use a metal plate. Wood is handy for its lightness, but it is liable to warp during the polishing operation, and so shift the discs; to obviate this, I screw a flat piece of slate to the face of the wooden block, with a few common wood screws.

The cement used for the glasses is either pitch hardened with some shellac, or common black sealing-wax. For a small series of discs, a block of about 2 inches in diameter will be found most manageable. The pieces of glass cemented on this are arranged symmetrically, leaving as little interval between them as possible. They are now roughed down on the zinc plate till they are all brought to one level; they are then washed with a nail-brush and well rinsed, and fine-ground on one of the laps, and next smoothed on a circular piece of cast-iron, but little exceeding the diameter of the block of discs. This smaller lap must be carefully ground to a true plane on the larger ones. A little of the finest washed emery and water is spread over this lap with a feather, and the glasses worked upon it in every direction, holding the lap in one hand and the block in the other, and occasionally turning both; this is continued till the emery begins to get dry, the glasses are then washed and wiped dry, and the smoothing proceeded with; but no more water must be applied to the lap. This is now moistened by simply breathing on it. In a few minutes the lap will again become dry; remove the block, and wipe all the emery away about ⅜ths of an inch from round the circumference of the lap; breathe on it again; continue the smoothing, and also wipe the emery away from the outside till, finally, scarcely any is left, and the glass is nearly finished on the metal itself. If this operation is properly conducted, the glass will have a transparent surface free from scratches and greys, and so near a polish that a few minutes only on the polishing lap will be required. But one rule must be strictly adhered to, viz., never to polish a glass surface with any scratches in it. It is worth while to spend any amount of time in smoothing rather than to do this, and the operation must be repeated again and again, till no scratch whatever can be discovered. It is quite evident that to obliterate a scratch by polishing, the whole surface must be worked away till the bottom of it is reached. This makes the operation long and very tedious, and is almost certain to injure the perfectly flat plane which has been obtained by careful smoothing.

It is a difficult and hazardous task to polish glass on hard metal, as the surface is very liable to tear up. Consequently, the usual system is to employ a soft and partly-yielding material, in which the particles of polishing powder may be imbedded. For facing the lap, I employ beeswax hardened with resin, and stir some finely-washed ochre into the melted mixture. The lap itself is simply a brass plate, about 3 inches in diameter, which screws on to the lathe mandril; some of the above material is poured on to this, and spread over a layer of about 1-16th of an inch thick. When cold, it is turned off flat, and, to make it perfectly true, the whole face is scraped off at once with a hardened steel-cutting straight-edge. An old parallel cotter file will answer the purpose, ground from both sides like a blunt knife, and finally corrected on one of the cast-iron laps with emery. A series of shallow grooves, about an eighth of an

inch asunder, are now turned in the wax, and some cross scratches made radiating from the centre, from which a piece should be taken out. The polishing powder, consisting of a mixture of crocus and putty-powder, before described, should be mixed in a small gallipot with plenty of water, and applied to the lap with a feather. The lathe is now run at a pretty quick speed, and the block of glasses worked over it in every direction with considerable pressure. If the smoothing has been properly done, as directed, a few minutes will suffice to give the requisite polish, which is seen to take place equally all over the glasses; but if any scratches should develop themselves, it is better to repeat the smoothing than attempt to polish them out. This same method is employed if the glass were one continuous plane instead of numerous pieces.

Fig. 7.

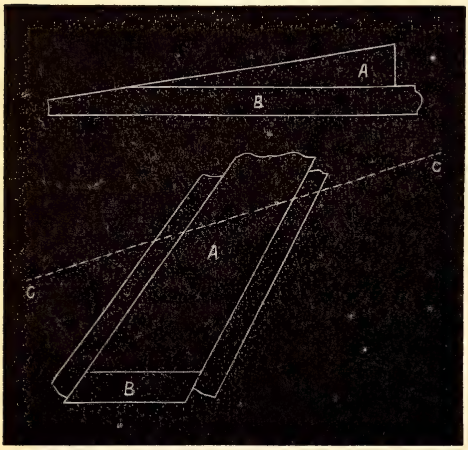

Fig. 8.

For minute prism work, where the size is required to be only just sufficient to transmit or reflect the pencils from a microscope object-glass, and the surface has to be perfectly up to a sharp edge, somewhat different practice must be adopted; for however carefully the smoothing or polishing may be performed, a rounding of the extreme edge always occurs. To obviate this, the edges must be guarded, as in the following examples:—A (Fig. 7) is a prism to be worked to a very acute angle. A piece of glass (Fig. 7), large enough for the purpose, having one side polished, is cemented with Canada balsam to a parallel plate of glass (B); they are then ground off together to the required angle and polished; the marginal error will be taken up by the lower end of the under plate. It would be impossible to make an acute wedge of this figure in any other way, and when separated it will be found to have a knife-edge perfect in the extreme.

Another example may be described from my practice in making the first prisms for the binocular microscope. A (Fig. 8) is an end view of the intended prism; this is supposed to have been a block of glass of larger size, with one polished surface cemented with Canada balsam on to the guard plate (B); the front and back reflecting surfaces are then smoothed and polished; these are then covered with guard-plates, and the top emergent surface of the prism ground off and polished to the dotted line (C, C). It will thus be seen that every corner of the prism is protected during the working, and is kept absolutely perfect to the edge. The prisms were made sufficiently long to be cross-cut into three or four. The smoothing was performed in accordance with the foregoing directions, but the polishing lap was required to be much smaller. The one I employed was only $1\frac{1}{2}$ inches in diameter. If a large lap is used, the polish is apt to commence on the margins of the glass; and if this is the case, a true reflecting figure will never be obtained. The polish should begin in the centre and spread to the outside. The proper angles for these prisms were set off by a graduated steel sector, and, as the measurements have to be taken from the back of the guard-plates, it is necessary that these should be exactly parallel; if not so, they must be ground on the surface-laps till all the edges gauge alike.

I may here remark that I am merely recording what has been my own self-acquired practice, and which is perhaps neither the most expeditious nor easy. My best apology must be, that I have always secured perfectly accurate results by these methods, and when a few only are required, I must confess that I do not

see a better way. But the great demand that has arisen for binocular prisms has induced the makers to discover a plan of working them in blocks, a number at a time, the particulars of which I do not pretend to explain.

Some very excellent prism work is produced on the Continent, and as the mode of polishing is peculiar, it may be worth while to record it. Chevalier & Co., of Paris, through Messrs. Beck, politely sent me an explanation of the process, together with a sample of all the grinding and polishing materials used in their business. After the surface of the prism is smoothed, a piece of very thin, smooth paper (much resembling photographic negative-paper) is cemented by its extreme ends with a little gum or dextrine to the metal lap; a lump of yellow tripoli (labelled "Tripoli de Venise") is then rubbed dry over the paper, and the prism, also dry, polished thereon by hand movement; generally not more than two or three applications of the powder are required. I have tried this method with the identical paper and polishing material, but must state that, in my hands, the result has not been satisfactory for accuracy, at least in very small prisms; for larger ones it may answer better.

Management and Selection of Aquaria.

BY A. W. ROBERTS.

I CANNOT urge too strongly the wisdom of beginning the study of aquaria on a small scale at first, so that the fundamental principles may be mastered before much money has been expended on a large and expensive tank, which will, in all probability, result in discouragement and failure.

For the first lesson I would advise the use of a candy jar (see engraving). Having filled it with soft water, expose it to the full action of sunlight from two to four days, at the expiration of which time the spores of various kinds of confervæ contained in the water will have been developed, and the inside of the glass jar will have become thickly coated with confervæ. Continue to expose the jar to the full force of the sun's light and heat ray's, no matter how high a temperature the water may attain, and a second development of plant life will take place, which will be known by the water becoming of a thick opaque green color, from the presence of millions of microscopic plants, which have the power of moving about in the water. These facts, and many

TALL JAR FOR AQUARIUM.

others which might be cited, go to prove how universal is the diffusion of the spores or seeds of low forms of animal and plant life, which only require the proper conditions of light, heat and air to develop them.

We will now take this jar and place it where it will receive *cool diffused daylight, but no direct sun rays*, and will also place a dozen snails in the jar, a fresh-water mussel, and a small bunch of mermaid-weed. In three days the water will have become perfectly clear. In consequence of the lowering of the temperature of the water in the jar, caused by depriving it of the direct action of sunlight, the green coloring substance, or locomotive plants, contained in the water, have ceased to exist as living plants, but their remains may be found deposited on the bottom of of the jar in the form of a dirty-looking loose brown substance. This deposit of decayed vegetable matter is termed "humus," and is quite harmless in an aquarium. The fresh-water mussel has also helped to destroy immense quantities of these vegetable organisms, and if you watch him with a magnifying glass you will see a constant stream of water loaded

with debris being drawn into his syphonal or feeding tube. The snails have not cleaned off the confervæ on the sides of the glass to any great extent, except in streaks here and there, where they have rasped it partially off with their lingual ribbons. We will now envelop the jar in a wet towel to within an inch of the surface of the water. This will reduce the temperature of the water, and at the same time reduce the amount of light passing into the jar. The mermaid-weed will throw off enough oxygen to support the animal life contained in the jar for two days, for which length of time we will leave it. Before the expiration of two days all the conferva on the glass will have died and passed into the condition of humus. This result is caused by the reduction of the light, and the lowering of the temperature of the water, caused by the application of the wet cloth. The snails will now be seen going over and over the gravel at the bottom of the jar, particularly the Planorbis snails, in search of any remaining dead vegetable matter and conferva, of which they are very fond.

The water has now become as clear as crystal. Not a vestige of these billions of plant organisms is to be seen—all have been eaten by the snails and mussel, who have converted them into harmless earthy excremental deposits.

We will now go over the ground once more, just to see what this first lesson has gained us in knowledge. First, then, we have the positive proof that all pond, river, and rain water contains immense quantities of the spores of low and minute vegetable organisms, which are ready and waiting to be developed into visible growths whenever the conditions of proper resting places, light, and heat, are given them.

Secondly, that whenever, from excess of light and heat, these vegetable organisms are developed too fast, causing the tank to look unsightly, they may be overcome by removing the causes that produced them; that is, by decreasing the amount of light (not wholly cutting it off), and at the same time lowering the temperature.

Thirdly, the utilizing of molluscs in an aquarium, but not to the extent of expecting them, unaided, to clean the glass of all vegetable growths, as has been so often stated in books on aquaria.

Fourthly, the nature of decaying vegetation and its affording food for snails.

Fifthly, the harmlessness of excremental substances, and even their positive benefit in a fresh-water aquarium.

Sixthly, and above all, the great error of *piling water up* instead of *spreading it out* and exposing it on all sides to the action of light and heat.

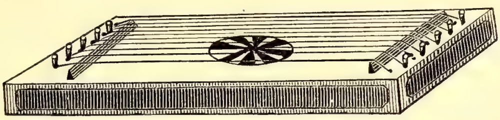
The Æolian Harp.

THE season has come when open windows are pleasant, and we invite into our houses the cooling breeze loaded with the perfume of flowers. To the fragrant air of the garden it is easy to add the wild melodies of nature's music, and we propose to tell our readers how to do it.

The Harp of Æolus is supposed to have been invented, or at least greatly modified by the famous Kircher, who named it after Æolus, the god of the winds. It consists of a long box, such as that shown in the engraving, made of any light wood, good clear pine answering very well. The length of the box should be the same as the width of the window in which it is to be placed, and it may be five or six inches wide, about two deep. The top of the box is strengthened at the ends by nailing or glueing an extra piece on it so that it may hold more firmly the pegs used for fastening the strings, and there is at each end a bridge similar to the bridge of a violin. As the top of the box forms a sort of sounding board, there is a hole cut in it, as shown in the figure.

There may be from one to twenty strings—five being a very good number. They are stretched over the bridge and fastened at each end by means of pins, just as is done in the violin. When these strings are in unison, and the instrument is exposed in the window to the action of a gentle breeze, they will emit the most agreeable combination of wild and melting sounds, changing from one harmonic of the string to another, according to the varying impulse of the wind, and its unequal

action on the different parts of the vibrating strings. In the Æolian harp constructed by the Rev. W. Jones, the strings, instead of being on the outside were fastened to a sounding board within a wooden case, and the wind was conveyed to the strings through a horizontal aperture. Such an instrument might be used even in the open air. Dr. Young says: "To remove all uncertainty in the order of the notes in the lyre, I took off all the strings but one; and on placing the instrument in a due position, was surprised to hear a great variety of notes, and frequently such as were not produced by any aliquot part of the string; often, too, I heard a chord of two or three notes from this single string. Discords are also often heard from the unison strings of this instrument; the cause of which is evident from the manner in which the notes are generated; for the aliquot parts of a string contain in themselves an infinite variety of discords."



ÆOLIAN HARP.

Zincography for Amateurs.

IN a recent paper read before the London Society of Arts, Mr. Thomas Bolas, F.C.S., described zincography as a simple and easy mode of printing in the following fashion: Zincography, he said, is similar to lithography, except that a zinc plate is employed in the place of the lithographic stone. The so-called transfer paper is merely a moderately fine paper which has been brushed over on one side with a mucilaginous mixture, prepared by boiling together the following: Water, 1000 parts; starch, 100 parts; gamboge, 6 parts; glue, 1 part. This paper is written upon with the ordinary commercial lithographic writing ink, which has been rubbed up with water like an artist's water-color. The writing being dry, it is necessary to moisten somewhat the back of the transfer by means of a damp sponge, after which it is laid face downward on a sheet of ordinary roofing zinc, which has been previously cleaned by means of emery cloth. Both being now passed together under the roller of a small press, the transfer adheres to the metal plate; but on damping the back of the paper it becomes easily removable, leaving the writing on the zinc. The face of the zinc plate is now gently rubbed over with mucilage of gum arabic, which is all the better for being slightly sour, and the excess of gum having been sponged off, an india-rubber inking roller charged with ordinary printer's ink, is passed over the still damp zinc plate a few times. The ink takes only on the lines of the transferred writing, and it is merely necessary to lay a sheet of white paper on the plate and to pass both through the press to obtain an impression—an exact reproduction of the original writing. Any number of copies can be printed by repeating the operations of damping and inking. The zincographic process, thus simplified, is rapid, economical, and within the reach of every one.

Antique Bronzing and its Imitation.

The deep green, blue, and blue-green covering of copper and bronze which develops under the influence of dampness and air, is technically called patina, and consists of carbonate of copper. It has been observed that bronze statues in large towns are no longer covered with this patina, but turn black, while those statues which have been erected in the country and in parks are still covered with the greenish covering. Some kinds of bronze turn green sooner than others, which is specially the case with those containing much zinc, little lead, and no tin. The principal thing, however, in a statue, is a clean surface, which has been obtained by filing, etching, and polishing, and which is retained by frequent washing with water. In some places

the surface is kept clean by being rubbed down once a month with olive oil. The artificial patina is obtained by first cleaning the bronze and then dipping it into a solution of vinegar and water, after which it is exposed for some weeks to the influence of damp carbonic acid gas. Or the bronze may be painted with a solution of 4½ parts sal-ammoniac, and 1 part oxalic acid, in 94½ parts distilled vinegar. The modern imitation patina, to be seen on lamps and statuettes, can be produced by using a paint consisting of carbonate of copper and light spirit varnish (sandarach lacquer or photographic negative lacquer); this greenish lacquer is then put on the objects to be treated, with a brush, like paint. The green paint then collects in the recessed parts, and, when dry, looks like patina. This proceeding is specially to be recommended where objects with imitation patina have been damaged and are to be restored. Carbonate of copper gives a bluish color—verdigris (acetate of copper) a light green shade. Intermediate tinges are obtained by mixing the two.

THE MOON, II.

Directly north of Mare Crisium (A), in the first or N. W. Quadrant, is a large number of walled plains or ampitheatres. Their interiors bear a perfect resemblance to the outside grey plains, like a great entrenchment thrown around an undisturbed surface.

The ring or wall is usually steepest within, and in many instances built up in vast terraces, each terrace evidently marking the ancient level of a molten lake. High peaks occasionally spring up from the wall, like watch towers, and gateways break through the rampart.

Close upon the northern border of M. Crisium is the walled plain Cleomedes (12), 78 miles in diameter. It includes a small brilliant crater. North of 12 is Burckhardt (19), 35 miles in diameter, the interior being 12,700 feet below its east wall. Geminus (20) is 54 miles broad, and the wall upon the east side is 12,300 feet high, and the western wall 16,700 feet high. At the west,

and close to 20, is a small ampitheatre (21), having walls of the same height as 20, but far more precipitous; it is called Bernouilli. To the right or west of 21, and very close to the limb of the Moon at full, is Gauss (22), a very conspicuous object near sunset, when the shadow of its mighty wall on the west is thrown across the interior plain, enshrouding the base of its central mountain, while the inside of the eastern wall is bathed in sunset's golden rays; it is 110 miles long.

Endymion (27), Atlas (28), and Hercules (29) are three large walled plains, situated about 32° from the north lunar pole in the N. W. Quadrant. 27 is 78 miles in diameter, and its irregular wall in some places more than 15,000 feet, "overtopping all but the very highest peaks of the Alps." It is best seen 3d. 7h. after New, and 2d. 9h. after Full. Atlas is a grand ampitheatre 55 miles broad, containing 460 square miles. Its ring rises on the north 11,000 feet, and is exceedingly rich in terraces and towers. A small and very dark spot is near the centre. Hercules is the companion of Atlas, being only a few miles east. It is 46 miles across, and the ring is *double* in places. Best seen 5 or 6 days after New, or 3½ days after Full.

South of these are several incomplete rings, all opening northward. At the right of 27, Mare Humboldtianum (B) forms part of the W. Limb, and the peaks of its border sometimes appear in profile 16,000 feet high.

Penn Yan, N. Y.

What Old Triangular Files Can be Used For.

TRIANGULAR files when worn, are generally thrown aside as worth but very little except for old steel, but their sphere of usefulness need not end here.

Probably one of the most curious uses to which such a file can be put is that it can be made into a very good glass cutter. Grind the three sides at the point smooth, so that the teeth are obliterated. Grind the sides flat, but shape the point curved or convex. To use it, hold the tool so that one of these sharp rounded edges will bear upon the glass, and with a little pressure, draw it steadily over the glass. The result is a slight scratch or cut, and by using a little force the glass will break where this scratch is seen.

If the teeth of an old file be removed by grinding, and the taper shape be preserved, it will make a passable hand reamer. If the point be made obtuse or "stunt," it forms a convenient substitute for a hand countersink. If the tool is put in a hole that is to be enlarged it will be observed that there is an equal bearing at the three points, which gives a steady hold on the metal to be removed. Now turn the tool a little so that it will cut. Observe the position and shape of this cutting edge. To the initiated it will present about the same form as that of the cutting edge of the tool used by the machinist to cut iron in the lathe.

The form of the file being three-square, or triangular, the edges present an angle of 60 degrees. This is the strongest and best angle known to cut iron and the hard metals. This same angle is used by the machinist to shape the points of his lathe centres, and also to make the indents in shafting and the work to be put on these centres to be turned. It may also be mentioned that screw-threads, when correctly made, have this same angle. It may very properly be called "the angle of strength."

As a scraping tool to remove an amount of metal in a short space of time, the old file, when properly ground, has no equal. It can be used to scrape out curves and hollows and finish rounds and swells. No other shaped tool would answer as well.

If ground after the manner of a graver, the old file can be used as that instrument, answering all that may be required of it, being capable of producing much good work.

As a hand turning tool for working iron, brass, ivory, bone, the softer metals as well as the harder woods, it makes a most excellent tool. One form may be made by grinding the sides smooth and making the point sharp. The tool then presents three cutting edges, and serves some of the purposes of the diamond-pointed tool. If the file be ground at the end with three obtuse cutting edges, it can be used precisely like the diamond-pointed tool, and is very strong and durable for cutting metals. If the file be broken off square and only one cutting edge be made across the broken end, it will make a useful turning tool for some purposes.

One great advantage in using old files of this kind for tools is that the file is already made and shaped to receive the handle, and is tempered the entire length to the commencement of the tang. Renewing by grinding will produce a cutting edge with no occasion to harden and temper. Its cost to be made into a very good tool is very little. As a general thing, other tools are tempered but a short distance from the cutting edge, and after being used enough to have this worn or ground away, the temper must be renewed.

In selecting old files for tools it may be borne in mind that as a general thing coarse-cut files or files with coarse teeth are make of a grade of steel not so fine as those that are made with fine teeth. As a hint to get a good tool, select an old file that is cut with fine teeth.—*Blacksmith and Wheelwright.*

EXCHANGES.

Wanted, "Butler's Family Aquarium;" will give in exchange two books, entitled "Laughing Gas" and "De Walden's Ball-room Companion." E. R. Brown, Box 25, Covington, Ind.

A small printing press and outfit, cost $12, for steam engine, Demas lathe and scroll saw, or offers. Ernest Corthell, Rockport, Maine.

A patent spectograph, cost when new $1.25; rare minerals, birds' eggs, and postage stamps, to exchange for minerals, foreign coins, Indian relics, or offers. Frank F. Fletcher, St. Johnsbury, Vermont.

Eggs, of the English sparrow, for good specimens of other birds' eggs; botanical specimens mounted and unmounted to exchange; lists exchanged. C. R. Hexamer, New Castle, Westchester Co., N. Y.

Two telegraph instruments, nearly ½ mile of wire, one battery; also 4 in. magnet. 8 Scientific American Supplements, full of information; new history of United States; a $4 German silver-trimmed flute; what offers? Ewing McLean, Greencastle, Ind.

Wanted, The Workshop Companion; I have Gaskell's Compendium, $1; The Round-of-Months, 75c.; Amateur's Hand Book, 15c.; also books, papers, pictures, etc.; send lists of what you have to exchange. W. B. Moore, Morgan Station, Ky.

McAllister's magic lantern and 30 pictures (cost over $95), to exchange for job type and material, or a good microscope and specimens; $20 worth of novels for a good $15 or $20 household microscope; rare mineral and Indian relics for exchange or sale; refers to editor. John T. Patrick, Wadesboro, N. C.

What is offered for one of the Climax extension step ladders? H. E. Phelps, Manhall, Michigan.

Wanted, a good microscope in exchange for a scroll saw; instrument must be in good order, and magnifying power of from 200 to 300, or 400 diameters. H. E. Rhodes, Brighton, Iowa.

To exchange, a $3 microscope for some old issues of Canada postage stamps. Wallace Ross, Lock Box 97, Rutland, Vt.

Wanted, a printing press; have for exchange a good microscope (Smith & Beck, London), 3 object glasses, and three eye pieces, power from 15 to 600 diameters, original cost $60; books, chemicals, guitars, and other things for exchange. E. F. Underwood, 9 Murray St., N. Y.

Wanted to exchange, Colorado minerals, such as jasper, smoky quartz, silicified wood, etc., for good specimen fossils, or perfect crystals of minerals of other localities. H. F. Wegener, Denver, Colorado.

One Natural Philosophy, one Bryant & Stratton's Counting-house Book, and two long bows, with arrows, to exchange for cabinet specimens or curiosities. W. D. Wright, Lock Box 17, Bremen, Indiana.

Wanted, coins, minerals, and type; send lists of what you have and what is wanted in exchange. A. Campbell, Derrick City, McKean Co., Pa.

An Excelsior Printing Press, with equipments, comparatively new, cost over $47, for double barrel breech-loading shot gun, with reloading tools and shells. William A. Hervey, Box 134, Taunton, Mass.

To exchange, 400 stamps, all different, in a stamp album, for a small printing press with type, etc. Arthur D. McGerald, 106 Bird Ave., Buffalo, New York.

Revolver, microscope, microphone, 4 magnets, skates, skate sharpener, copying pad, books, magazines, $7 worth of rosettes, and lots of other things to exchange; I will give you a better trade than anyone else can. Chas. T. Conover, Esperance, Scho. Co., N. Y.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Photographs of ten of the most influential Indians of Spotted Tail Agency, including Spotted Tail and family and four oil chromos, very beautiful, for printing press, scroll saw, or offers. Luther Emerson, Creighton, Knox Co., Neb.

"Appleton's Picturesque America," never been read or handled, value $24; "Dana's Mineralogy," $10, and coins, to exchange for a breech-loading shot gun, Winchester or Evan's rifle, or offers. D. M. Fuller, Box 115, Camden, Maine.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

One pair best steel climbing irons, handsome seven shot, 22 calibre revolver, full nickel plate, ten dollars worth of boys' papers, and magazines, for works on natural sciences or offers. W. M. Stribling, Circleville, Pickaway Co., Ohio.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho,

Dumb bells of all sizes, to exchange for most any thing; send for circular containing weights of them to J. P. Donohue, Box 7, Davenport, Iowa.

Wanted, scientific books and papers, microscope, drawing instruments, telephone, stamps and coins, in exchange for scroll saw, type, cards, revolver, shot gun, magazines, scientific books, or almost anything. W. L. Goodsell, Bath, N. Y.

A pair of New York Club skates, worth $3.50, also coins, minerals and postage stamps, for books or offers; correspondence invited. E. F. Greene, P. O. Box 889, Bath, Steuben Co., N. Y.

A nice marine oil painting, ready framed, worth $5.00; state what is offered in exchange. C. Hammond, Artist, P. O. Box 47, Chatham, Barnstable Co., Mass.

Photographic camera, one portrait and one landscape tube, with chemicals complete, in exchange for medical books. J. Frederick Herbert, 1,324 Poplar St., Philadelphia, Penn.

What offers for 1 Household Microscope, one 8 shot breech-loading carbine, 1 new 7 shot pistol and cartridges, 1 small gold watch, 1 small gold chain, 1 violin and case, one new darning machine. Lock Box 147, Tarboro, Edgecombe Co., N. C.

Back Nos. "Penman's Art Journal" for 1879; Gaskell's Compendium, $1; Coe & Shells' Pen and Ink Drawing, 25c.; Pettengill's Fortune Teller, 40c.; Hand-Book of Business, 25c.; in exchange for microscope, printing press, or offers. M. B. Moore, Morgan Station, Ky.

Trump's and Russel's scroll patterns, worth $10; for large lenses preferred. H. J. Peters, Rogersville, Ohio.

Lessons in Standard Phonography given in exchange for a printing press, lathe, scroll saw, scientific books, hammock, or offers. Phonographer, Box 331, Topeka, Kans.

Wanted, chemical apparatus, in exchange for "Phrenological Journal," $2, and the last six numbers of "American Agriculturist," 75 cents, of 1879. T. P. Potts, Canonsburg, Pa.

Land and fresh water shells, birds eggs, minerals, fossils (correctly named), or books, Gray's "How Plants Grow," Pope's "Linear Perspective Drawing," in exchange for a Multum in Parvo

Management and Selection of Aquaria. II.

BY A. W. ROBERTS.

IN a previous article we studied experimentally the effect of light and heat on the vegetable spores and germs which are contained in almost all water. We will again fill the jar up to the rim with fresh water, and then take a wash basin or any shallow vessel of earthenware or wood, and pour into it the same amount of water that is contained in the jar, seeing that the water in the shallow vessel is not less than three inches in depth. We will now place both vessels in a shady (not dark) position, where no direct sun rays ever reach them. Into each vessel we will place a small sun-fish or striped dace (*not Pigmy dace, eel, or gold fish*) of as nearly equal size as it is possible to obtain. We have now got each vessel, as regards the size of the fish and the amount of water and light, exactly alike. The dace in the glass jar for the first twenty-four hours will remain at the bottom; during the next twenty-four hours he will have changed his position to the centre of the body of water contained in the jar, and in the next twenty-four hours he will be hugging as close as he can get to the surface of the water; he will have lost his color, and will be gasping, weak, and tired. And in a few hours more he will be found dead at the bottom of the jar, or in the agony of suffocation he will have jumped out.

We will now examine the dace in the wash basin. Oh, he looks splendid! How active he is. How bright his colors; and perhaps he will take a small piece of angle worm; yes, he has taken it, and is looking for more—a sure sign of perfect health in a fish. How long will he live in that water without its being changed? A week, unless the atmospheric temperature increases.

Now what does this go to prove? First, that in aquaria, or vessels made for con-

fining fish, where the water remains unchanged and at rest, the water should be spread over as great a surface as possible, and at the same time should present a reasonable depth for the perfect display of the animals.

In the case of the glass jar, surrounded on all sides with light, the water becomes warmer than that in the wash basin, and as a consequence it is in a condition to take up less oxygen. Fish placed in vessels composed entirely of glass, become greatly woried and excited for the first few hours, caused by glare of light on all sides, in their vain attempts to pass through the glass and thus make their escape; and then, again, they are under constant alarm, caused by the moving objects that surround them. Under these exciting conditions they breathe much faster, and consequently exhaust the oxygen more rapidly than when in a natural condition.

I know a scientific gentleman who some years ago kept a fresh-water crayfish for over two years. It must be remembered that this crustacean is considered by dealers to be one of the most difficult animals to keep in stock. The secret of his success was entirely due to the shallowness of the water in which the crayfish was kept. I will quote his own words:

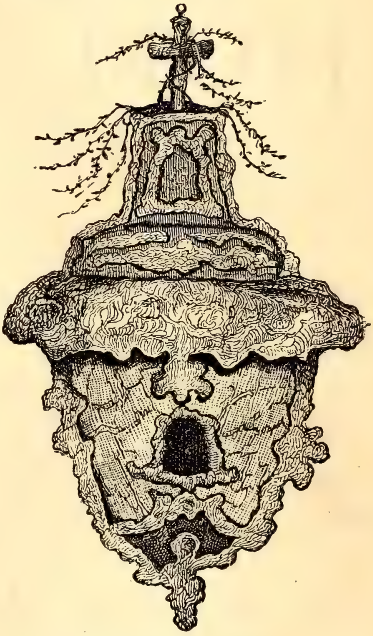
"I have succeeded in keeping a crayfish for over two years, which I have kept in water not more than an inch and a half deep, previous experiments having shown that in deeper water these animals always died in course of time for want of sufficient aeration. His appetite during the two years was always good. *The water was never changed,* but some was occasionally added to supply the loss by evaporation. Had this crayfish not met with an accident it might have lived many years longer."

I had, on one occasion, a number of dace live and do well in a long tank where the water was shallow, and stood during the day at a temperature of 78° Fahr.

It is well to remember that air dissolved by water is always richer in oxygen than the atmosphere breathed by terrestrial animals. One-third of the air absorbed by water consists of oxygen, instead of only one-fifth, as is present in the atmosphere.

A Hanging Bird House.

THE bird house represented in this figure is constructed out of a combination of flower pots and old milk pans, arranged so as to resemble, in form (when coated with plaster of Paris), an acorn. The top consists of a five-inch flower pot inverted, which has the bottom cut out. This pot is fastened to an old milk pan; this pan is fastened to a larger-sized pan, the rim of which extends over a 14-inch flower pot. The small flower pot and the tin pans are to represent the cup of the acorn, when coated with plaster of Paris. The 14-inch pot is to represent the nut of



HANGING BIRD HOUSE.

the acorn. Both pans are punched full of holes, so that when the plaster is laid on it will pass into the holes and clinch, otherwise it will not adhere to the smooth surface of the tin. Holes are made in the bottoms of the pans and the large pot, for a turned picket or stick to pass through; at the bottom of the large pot a hole is bored through the picket into which a pin of iron or wood is inserted to prevent the pots and pans from slipping off. In applying the plaster to the pot I

use an extra quantity where the pots and pans join together. The bottom of the 14-inch pot was extended with plaster, so as to form the point of the acorn. The interior of the large pot was divided into two compartments, holes being cut into the sides of the pot for entrances. These holes are easily cut with an old knife made into a saw by "hacking" it.

In ornamenting this bird house I took advantage of the subdued red color of the pot, which I slightly veined with plaster. The rough coating is applied with a broad-bladed table knife or "pointing" trowel. After the plaster is dry, a coat of sombre green paint is applied. Where the stick passes through the top pot a cross is formed by nailing on a cross piece. The small inverted top pot is filled with earth, and planted with tradescantia or German ivy.

Under the eaves, formed by the projecting pan, numbers of holes were bored through the pot and into the compartments, to secure sufficient ventilation inside.

This bird house should be suspended from the branch of a tree by means of a stout wire attached to a strong screw eye, firmly inserted into the rod which passes through the centre of the house. The end of the rod should be firmly bound with annealed wire to prevent its splitting, and the iron hook should be heated and dipped in melted grease before being screwed in. This will prevent its rusting and losing its hold. Rope or sash line should not be used for suspending the house, as they are apt to rot and break, and besides this they twist and untwist, and so cause the house to twirl round, making it unsteady.

Home-Made Telescopes and Microscopes.—VI.

ON THE PRODUCTION OF SPHERICAL SURFACES IN GLASS.

AS the radii required in the construction of microscopic object-glasses are seldom very long, the templates for all sizes above 1-5th of an inch in diameter are usually made of steel, such as thin saw, spring, or busk-steel, not softened, but turned hard, as obtained. A hole is punched through the middle of a square plate with a centre punch, the hole is then rounded out with a taper rimer. The piece of steel is next broken round as near as possible to the size of the circle required, by clamping it in the vise and driving off the surplus metal round the edge with a chisel held close to the jaws. This steel plate is driven on to a mandril so as to turn true without any wabble. The lathe is run at a low speed, and the T-rest placed rather high near the top of the work, which is turned true with the common square graver held over-hand. The chamfered edge of the templates may form an angle of 90°. Every convex template should have its counterpart or concave; the steel plate to form this is clamped flat on to a face-chuck by a ring with two opposite screws tapped into the plate. The inner circle is turned out with a side tool, consisting of an old saw-file ground to a point on the three faces. The turning is continued till the disc or gauge just drops through; the inner edge is then chamfered from both sides.

Gauges below 1-5th of an inch in diameter are made from steel wire turned to the form shown in Fig. 7. The disc end is

Fig. 7.

hardened by heating it with the lamp and blowpipe, and quenching it in oil, and the counter-gauges are most easily formed by a counter-sink rose-bit run in the lathe. The plate of steel is chamfered out alternately from opposite sides, by forcing it up on the socket of the back centre, till the disc will pass through; the hollow templates are, of course, cut in half before they can be used.

An instrument for measuring the diameter of the discs, etc., is indispensable. It consists of a pair of sliding steel jaws, with a vernier and nonius capable of being read off to thousandths of an inch, and is sold by the watch tool makers.

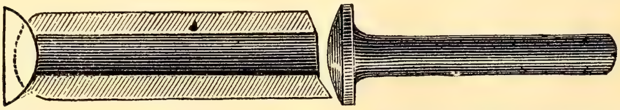
The moulds for grinding minute lenses are always of brass; they are also used in pairs. The concave is turned out to

gauge, and the convex to the counter gauge. For small radii the hard gauges are finally used for the last correction, as a turning, or rather scraping tool, and finished by grinding the two moulds together with the finest emery.

There is some difference in practice between the grinding of lenses for long and short radii. In the former, as for telescopes, the glasses are fixed, or have but a very slow rotary movement, and the concave tool is worked over them, either several at a time in blocks, or else, if a shallow curve is required, only on one single disc; this is placed in the centre, and a number of smaller pieces of glass planted round the circumference to support the figure, the whole being ground as one. But in the lenses to which this paper particularly refers, the concave tool is invariably caused to revolve rapidly, and the convex lens worked into it.

and tube ground and polished off together, as shown by Fig. 8 *b*, taking the same precautions as before to work the lens up to the exact diameter required. The end lines show the rough disc as cemented down. By this method all the marginal errors are taken up by the glass tube-holder, of which an assortment of various sizes will be required, from a minute bugle up to half an inch in diameter. Before using the holders again for other lenses, the end must be ground out on each occasion, so as to increase the diameter of the cup. The lens, when taken out by being warmed, will have a knife-edge perfect in the extreme.

In minute lenses, some difficulty will be experienced in obtaining the measurements by means of gauge instruments, when near the right diameter. I therefore, for small sizes, always use the microscope with micrometer eye-piece, hav-



b *a*

Fig. 8.

The same rules for guarding the extreme edges of lenses should be observed, as described in prism-work, shown by the following examples. Fig. 8 *a*, represents a plano-convex lens which has been made and finished upon a flat disc of glass, to which it has been attached with hard Canada balsam. The two discs are cemented to the stick with black sealing-wax; the lens and supporting disc are rough ground on the zinc plate till they nearly fit the concave gauge; they are then ground in the brass mould till the lens measures very nearly the diameter required, leaving a small allowance for smoothing and polishing.

For double convex lenses, the disc of glass, cemented on a stick as usual, is first ground and polished on one side. A piece of glass tube of suitable size is selected for a handle, and the end of the bore ground out to a similar radius; the polished side of the unfinished lens is then cemented into this concavity, and the lens

ing previously taken the exact size from the diameter of the cell in which the lens is to go. This is very accurate and convenient. After the finished lens is taken out of the holder, if it should be found too large to enter the cell, it may be slightly cemented to the end of a wire, and twisted into a piece of the finest emery paper, held in a hollow form, and the keen edge is taken off till it passes through.

The single fronts, for the highest powers, from their form, do not admit of being ground in this way. A piece of brass or steel is screwed into the mandril, and the end turned of a size to enter the cell into which the lens is to go; the end is turned flat, or rather slightly hollow, and the centre taken out. A piece of crown-glass is cemented by its polished side to the flat end, with the best orange shellac, and turned with the diamond point till it nearly enters the cell. The last finish may be given by fine emery paper wrapped round a flat piece of hard wood. The ex-

treme end of the glass is then turned off flat, till it equals the thickness of the intended lens, from the apex to the flat, as measured by the jaws of the gauge; the lens is next turned off by the diamond to the curve required, as shown in Fig. 9;

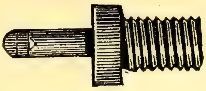


Fig. 9.

and, finally, the chuck is removed, and the lens ground and polished in the mould as usual. In all cases of cementing lenses on to chucks in this way, care must be taken that they are well pressed down, so that the layer of cement may be of the same thinness all round, otherwise the lens will be tilted and out of centering from unequal thickness. When taken off, the lac may be cleaned off with alcohol.

A similar mode of chucking is employed for a plano-concave lens. The polished flat side of the flint glass is cemented to the chuck, made just to enter the cell; but in order to appreciate the thickness in the centre, the circumference of the disc, after it is turned to fit the cell, is polished with a piece of hard wood and crocus. The concavity is then turned out a trifle deeper than the radius of the circular gauge till a mere line of light only is observable by looking through the polished edges. The chuck is then removed from the mandril, and the lens thereon ground and finished on the convex tools.

For a double concave lens, such as is used for a triple back, the end of the chuck, instead of being flat, must be convex, to match the radius of the concave surface of the disc of glass that it is to receive, this having been previously ground out and polished independently in the

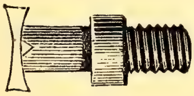

Fig. 10.

usual way of cementing it on to a stick; but as the curves are shallow, it is best not to turn the disc down to the intended size at once, but leave it much larger than the cell or chuck (Fig. 10), and after it is polished as before directed, the chuck is again screwed into the mandril, and the lens turned down so as to fit the cell; this is done in order to avoid the marginal errors which would arise from working a shallow curve of small diameter.

The same precautions have to be observed in smoothing lenses as directed for prism-work; the finest emery is used, and the requisite moisture applied as required by breathing on the lens, taking care that the accumulation of powder is removed from time to time from where the centre of the mould has been dug out, otherwise this may contain some coarser particles that may cause scratches.

As before remarked, the moulds are made in pairs; the convex and concave are turned to their respective gauges, and then ground together. The diameter of the mould should always rather exceed that of the lens intended to be ground; and the centre, or "pip," is taken out; unless this is done, a prominence is left at this spot, which injures the work. During the smoothing, the two moulds should occasionally be worked together, as this greatly tends to insure the accuracy of figure of the lens; and after this is completely smoothed, the moulds should again be matched, so as to leave them with a polished surface, for a reason to be hereafter explained.

Training Plants.

THOSE who have visited European gardens and pleasure grounds, must have been struck with the beauty of the trained plants, forming hedges and bowers, which form a prominent feature in the old homesteads. The wonderful skill shown in the culture and training of these plant marvels is surprising to those who are familiar with the vain attempts made in this country to grow live hedges. All along our country roads we see attempts to produce these live hedges, but in almost every case the result is a miserable failure. Although horticulture is not a subject to which we propose to devote much attention in these pages, yet since a nicely-trained hedge or arbor forms a pleasant work of art for our young

readers (whether boys or girls), a few words may not be out of place. And to show what may be done in this direction, we give an engraving of a remarkable specimen of ivy, cultivated and trained in a peculiar manner, and which was among the floral marvels at the Paris Exhibition of 1867. At that time the plant had a straight clean stem more than 6 feet in

TRAINED IVY PLANT.

height. The spread of the branches, when fully extended, would then have been between 32 and 33 feet, but they were trained in an arching manner, as shown, so as to leave an opening in the interior of about 23 feet in diameter. The branches were well furnished with leaves, and as the plant grew in a tub, it could be removed from place to place, and used as a pleasant summer-house. The facility of transportation was further increased by the fact that the branches were trained over wires, which could be folded up umbrella fashion.

Many similar tents might be made with other kinds of plants, such as Virginian creeper, common kidney bean, hops, and other plants that grow much quicker than ivy, but in that case, instead of a central stem, the pots containing them would have to be set on the outside of the circle, and the plants trained over a canopy formed of wire or wood work.

In training plants for bowers or hedges there are two points that specially demand attention. The first is cutting back or pruning. Most failures in hedge growing are due to the fact that the owners are afraid to cut the plant back. After a plant has made a fine growth, and has attained a height of six or eight feet, it seems cruel to cut it down to the ground. And yet this is just what must be done if we would have a hedge which is close at the bottom and free from gaps. The reason of this is obvious. The tendency of all plant growth is to the extremities of the branches, and if this tendency is allowed to develop, all the strength of the plant is drawn away from the buds near the roots, and they consequently die out, leaving nothing but bare poles. To form a good hedge we must have innumerable small shoots springing from near the ground, and not a few strong branchless stems.

The second point is that to enable the

plant to withstand this severe cutting back, the roots must be well-developed. Our climate is so dry, that unless the ground is deep the plants dry up and perish. The soil ought not to be too rich, but it ought to be very deep.

The same rules apply to the shaping of plants into bowers or arbors. A screen that will exclude sun and rain can be formed only by severe cutting, so as to produce a dense mass of fine branches.

Plaster Casts of the Face.

ALTHOUGH this is an art which is usually practiced by sculptors, and artists specially prepared for executing such work, yet it is not a difficult process and may be easily carried out by amateurs. The best way, according to *Stubchen-Kirchner* is the following: First anoint the hairs, eyebrows, and beard—if the latter is to be preserved—very thoroughly with pomatum or lard, until the hairs agglutinate, when they are to be arranged exactly as it is desired they should appear on the cast. All other parts of the skin are then oiled, and the head isolated from the rest of the body by suitably arranged cloths. A firm and well-waxed thread is now placed upon the head in such a manner that one half of it passes down the centre of the face, following the outline of the skin as closely as possible—and the other half passes over the back of the head, likewise closely following its contours. In the same manner another thread is passed over the head sideways, so that the whole surface is divided into four quarters. Good gypsum (dentist's plaster) is now mixed with warm water, the mass is allowed to become somewhat stiff, and then applied as quickly as possible by means of a broad brush, beginning at the back of the head and ending at the mouth and nose. In order to facilitate breathing, paper-tubes may be inserted into the nostrils, but, with proper care and skill, this is not necessary. Upon the first layer a second, of much greater thickness is applied with the hands, and just as soon as the plaster begins to set, the ends of the strings are grasped with both hands, and pulled outwards and upwards, so that the cast is divided into four parts. After a short time it will have hardened sufficiently to permit its being taken to pieces. The pieces are then dried and varnished. When using them for making a cast, they are placed in position and luted together with plaster. Direct application of a thick layer of fresh plaster to the skin of the dead often produces unnatural shrivelling of the skin, or twisting of superficial organs. To avoid this, it is best to apply first a very thin layer of plaster, then a number of strips of very fine cotton or linen fabric, and, after this first thin layer is dry, to apply a thick layer of plaster on top of the latter. The preparation of casts after the moulds are made is so simple that it needs no special description.

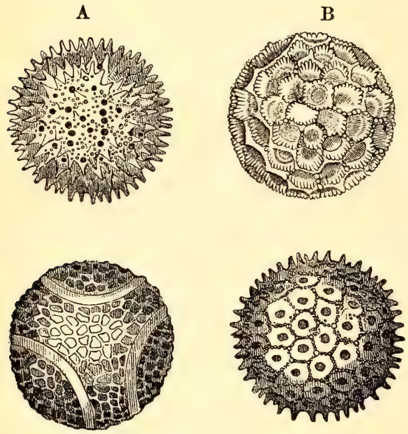
Pollen as Microscopic Objects.

THERE is scarcely any class of objects that yields more beautiful and more easily prepared specimens for the microscope than pollen and seeds Later in the season we hope to tell our readers of the beauties of the latter, but at present the gardens and fields abound everywhere with pollen, and we shall turn our attention to that.

To examine pollen under the microscope is not a difficult task. All we have to do is to shake a little on some smooth, dark surface, such as a piece of vulcanite or blackened paper, and examine it with a low or moderate power. The illumination must be good; good daylight answers well, but when we have to work at night we may get excellent results from the light of a good lamp condensed with a common condensing lens. The flowers of the hollyhock, the various lilies and other plants, all yield pollen differing widely in form, color, etc. It would occupy more room than we can spare to give the different appearances exhibited by the various pollens; we have selected four which will give a general idea of the beauty of this class of objects.

In the engraving the pollen marked A is from the Althæa rosea; B is that from Cobœa scandens; C from passion flower (Passiflora Cærulea), and D from Ifromæa purpurea.

While pollen requires little or no preparation for mere examination, it often puzzles the beginner to mount it so that it will retain its beauty. If we wish to keep it as an opaque object, it is necessary merely to dry it and mount it in a cell that is perfectly tight. The new wax cell is one of the best for this purpose, though the "cement cell," as it is called, is the most easily made and does not require any tools except the turn-table. The bottom of the cell should be made black, and this may be done either by pasting a piece of black paper on the under side of the



POLLEN GRAINS.

cell, or coating the bottom with some dark material—beeswax, colored black with very fine lampblack, being as good as any. The secret of success in preserving pollen in this way lies in thoroughly drying it, and a very excellent method is to take the whole anther, press it gently between sheets of soft, white paper, and dry it.

Pollen may also be mounted in Canada balsam, and for this purpose the balsam should be dissolved in benzole or ether, so that no heat may be required.

Those of our readers who have means for obtaining dark ground illumination, will find many of the pollens very beautiful when shown in this way. They shine like brilliant stars in a dark sky, and show their peculiarities and structure in a way that is wonderfully distinct.

Editorial Notes.

Complimentary if not Pleasant.

THE little book, entitled the "Workshop Companion," which we published last Fall, seems to have secured the complete confidence and approbation of the scientific and industrial press, for we find it copied everywhere, and we regret to be obliged to say, generally without credit. A recent issue of the *Scientific American* has a two column article on *Cements*, credited to some other journal. This article is the chapter on cements copied from our book *verbatim et literatim.* So, too, the Boston *Journal of Chemistry* quotes from the London *Pharmaceutical Journal,* an article on cements, which it characterises as "exceedingly valuable," and advises "all housekeepers, and those engaged in work in the industrial arts," to preserve the number of the journal containing it. Our readers will, therefore, be glad to know that they can have this article and many others of equal value, in very convenient shape by procuring the "Workshop Companion."

The article in question, contains much that is common property, but a very large part of it has been rewritten, carefully corrected, and the special circumstances in which the given directions are applicable are pointed out. Moreover, the introduction is entirely original with the author of the work. In slightly different form, it was published in the first volume of the *Technologist,* and has been probably quoted and stolen by more newspaper writers and book-makers than any other article within our knowledge.

Such general quotation and praise is certainly very complimentary, but would be more pleasant if accompanied with proper credit.

—Wood can be ornamented by punching down carefully in patterns, planing off a little, and then wetting; the parts punched down show in relief above the planed surface and make quite a puzzle.

Astronomy for Amateurs.

BY BERLIN H. WRIGHT.

(Calculated for the Latitude of New York City.)

THE PLANETS—JULY, 1880.

	D.	*H.*	*M.*

NEAR APPROACH OF MOON TO PLANETS AND STARS, AND OTHER PHENOMENA.

July 1. Saturn 8° South of Moon.
" 2. Uranus 6° " "
" 3. Moon midway between Pleiades and Hyades.
" 3. Earth furthest from Sun.
" 4. Venus 9° in Gemini.
" 4. Moon Perigee: Tide Highest.
July 4. Moon Highest.
" 3–6. Mercury brightest, being at greatest eastern elongation; 26° 19′. An evening star.
" 6. Mercury at descending node.
" 7. Moon about 5° South of Castor and Pollux.
" 7. Venus very close to the moon, being only about one degree north.
" 7. Eclipse of the Sun; Annular, invisible in North America. Visible principally South of the Equator in South America and Atlantic Ocean.
" 9. Mercury 3° North of Moon.
" 9. Jupiter 90° West of the Sun; quadrature
" 10. Moon 3° North of Regulus.
" 10. Mars 5° North of Moon.
" 11. Mars 26° in Cancer.
" 11. Uranus 6° "
" 14. Moon 2° South of Spica Virginis.
" 14. Venus, Superior Conj. with Sun.
" 18. Jupiter 19° in Pisces.
" 18. Moon Lowest.
" 18. Moon 2° North of Antares.
" 19. Moon in East Branch of Milky Way.
" 20. Moon Apogee—tide lowest.
" 20. Saturn 90° West of Sun; quadrature.
" 24. Venus in Perihelion.
" 25. Saturn 27° in Pisces.
" 26. Uranus 10° in Leo.
" 27. Jupiter 6° South of Moon.
" 28. Saturn 8° " "
" 29. Uranus 6° " "

*Mercury will set on the 5th, 1h. 26m. after the Sun, near the close of evening twilight and at a point 23° 47′ north of the west point, and 6° 53′ north of the sunset point. He will appear much as a first magnitude star; as Antares. He is near the middle of the constellation Cancer, and there are no stars in his vicinity bright enough to be mistaken for him.

THE MOON, III.

Mount Taurus (51) is a lofty range of high mountains, in which is the terraced crater, Rœmer (52), which is 26 miles in diameter, and 11,600 feet deep.

About six days after New Moon, Posidonius (54) makes a good object. This is a walled plain 62 miles across, including several small objects, in which changes have been observed by several astronomers. Mount Argœus (58) is a small range rising towards the East to a summit upwards of 12,000 feet high. It is remarkable for the spire of shade which it casts across the plain at sunrise. It requires close watching, as the shadow rapidly looses its slender point. It is best seen 4d. 21h. after New Moon. Macrobius (59) is an isolated crater, nearly 13,000 feet deep, and north of it is Proclus (60), whose ring is one of the most luminous portions of the Moon; best seen a few days after Full Moon. Plinius (61) is a terraced ring 32 miles broad, and filled with hillocks.

Menelaus (70) is the common radiant of several bright streaks. This is a steep crater 6,600 feet deep, and was declared an active volcano by the elder Herschel, but this was refuted by other

observers. It is quite probable that Herschel was correct in his surmise, as there is abundant proof of activity quite near this spot. 70 is very bright at Full Moon, and the surrounding bright streaks may be seen extending out into Mare Serenitatis (H), a nearly circular plain, 430 miles in diameter. Near its west edge is a low serpentine ridge, which may be best seen five or six days after New. Upon the south boundary of H is the grand mass of mountain peaks called Caucasus (75). The peaks tower as lofty as any on the Moon, reaching as high as 19,000 feet. Their narrow shadows are drawn out into fine points, forming a grand spectacle in the First Quarter.

Eudoxus (77) and Aristoteles (78) are a noble pair of craters, not easily seen at full, as the region is then dotted with thousands of bright specks. The terraced wall of 77 rises 11,300 feet above the west interior, and is crowned on that side by two turrets 15,000 feet high. 78 is more than 50 miles broad, and nearly as deep as 77, but with a much richer wall, being very remarkable for the rows of minute hillocks, which nearly surround it in lines, pointing to the centre of the crater; the finest specimen of this not uncommon arrangement. This same arrangement may be seen around 77 also, in the First Quarter. On the S. and S.W. of 77, down to Mare Serenitatis and the Caucasus, the surface is crowded with innumerable hillocks, like stars in the most crowded part of the Galaxy.

Penn Yan, N. Y.

Filing Flat and Other Surfaces.

THIS is one of the branches in which, as a rule, most amateurs fail, and failure is not confined to them, as it is one of the most difficult operations which the professional engineer has to perform. I think, therefore, a short practical article will be acceptable to many of our readers, and it will be my endeavor to make my remarks as concise as possible, and to convey as much information as space will admit of. First, then, as to the selection of files. This must, of course, depend entirely upon the nature of the material about to be worked. As to the various shapes and forms that are to be filed, these we will leave alone, *pro tem*, and be contented with trying to file a flat and true surface. This accomplished, whoever the person may be, he is entitled to consider himself a good vice-man, it being well known that this is one of the greatest difficulties connected with this particular art. Having selected a piece of brass to begin upon, about 2½ inches square, take a 10 inch bastard file One reason why I suggest brass to begin upon is that when the file is worn too much for brass it will be in good condition for steel or iron. Economy with files must form one part of the workman's education in filing. Some men will wear out twice the quantity of files that another will, and it is only because the one is careful and the other is utterly regardless of the files, simply because he does not have to pay for them. Before beginning operations, another important matter to attend to, is the fixing of the vice, and this should be so arranged that when the work is held in it, the surface to be filed will come to an elevation just below the elbow. Like many other things, there is a slight diversity of opinion as to the exact height it should be held. Some advocate the work being level with the elbow. I think it will be better for the workman to so adjust his work as to suit his own comfort, regardless of its being an inch above or below any given point. It may appear to some a matter of little or no consequence how a man stands in position when at the vice, but this is to me one of the best tell-tales of a good workman. Nothing is more objectionable to an experienced man than to see a fitter with, it may be, his left foot two feet or more from his vice, or, on the other hand, leaning against the bench and using two inches only out of a ten inch file. To be an efficient vice-man position must not be overlooked. The left foot should be about six inches from the bench, and the heel of the right between 30 in. to 36 in.; the left knee slightly bent forward, the elbows kept well into the side, and in taking the forward stroke, the weight of the body should go with the bend of the knee. As to the distance given for the feet, a deviation may be necessary in many cases in consequence of difference in the height of various men. But a few strokes of the file will soon show if the position is suitable. The file must be firmly held in the right hand, and the left hand should bear upon the front end of it, as the file must only be allowed to cut one way, that is, forward. The pressure must be relieved when it is drawn back; if not, much damage will be done to the file, in the way of breaking off the teeth. I have many times had men come to me with a file, and assert that it was of no use, being too hard, causing the teeth to break. Even so-called practiced hands have done this, but the cause of this has been not knowing now to use the tool. Nothing but long practice will enable any one to arrive at any state of perfection. In holding the file firmly in the right hand, it must not be clinched so that the wrist becomes cramped, but sufficiently rigid not to allow the file to turn all ways. The action must be a natural one, and the movements backwards and forwards be in a horizontal direction. After several trials, it may be found the same result has been obtained, that

of the work being rounded off at the ends, sides, and anything but flat. No matter; all the expressions of regret at this result, occurring so many times without any improvement, will not alter matters. Patience and practice are all that the tyro at the vice requires, and after a certain time he will find, probably to his surprise, that the piece he is filing is inclined to favor him by becoming something approaching flat. This is encouraging, and fresh vigor is instilled into the man, file, and apparently material, as a certain amount of improvement is evident at each successive trial. And I think that if, after a few months, for it will not be properly instilled into any one in less time, whoever tries can then feel certain of performing this feat of filing a flat surface, he will be well repaid for the time and study he has devoted to it.

To be Continued.

Labelling Bottles.

A writer in the *English Mechanic* says: "There is no plan so good as one I use. Affix a common paper label and let it dry; then heat the label (by a Bunsen burner or very small flame) till it will just melt paraffine rubbed on it. The label is absolutely protected, and looks as if it were enameled on the glass. If the neck and lip of the bottle and the stopper are similarly treated, a perfect air-tight joint is secured and the stopper never sets, while liquids can be poured out without running down the sides."

Practical Hints.

Case-Hardening.—If a surface case-hardened with prussiate of potash appears of a dirty black, it is because it has not been properly done, for a prussiate of potash, well-hardened job, is white, without a single shade of black anywhere, and is quite as hard as any case-hardening.

Again, any form of hardening that leaves the surface otherwise than white, does not thoroughly harden, or, in other words, the fancy colors on such work evidence that it is only partly hardened, and, as a rule, can be cut by the edge of a sharp smooth file, if well-pressed to the work.

These are facts none too well known, and just the points that your paper can do a world of good in bringing out.—*Blacksmith and Wheelwright.*

Cleaning Brass.—The following directions have been given by a correspondent of the *Artizan* (London):—Make a mixture of one part common nitric acid and one-half part sulphuric acid in a stone jar; then place ready a pail of fresh water and a box of sawdust. Dip the articles to be cleaned in the acid, then remove them into the water, after which rub them with sawdust. This immediately changes them to a brilliant color. If the brass is greasy, it must be first dipped in a strong solution of potash and soda in warm water. This cuts the grease so that the acid has the power to act. This is a government recipe used in the arsenals. We will add to the above recipe that first washing in clean water, and second in water in which aqua ammonia has been placed to neutralize all trace of the remaining acid upon the surface of the brass, is an improvement upon the above process, which is in all other respects, a good one. After dipping in the ammonia water and cleaning in the sawdust, if a good quality of lacquer be used, the effect is very fine. This process is excellent in preparing brass labels stamped from thin sheets.

Flower-pots in the Laboratory.—A flower-pot makes an excellent lamp screen, for steadying and concentrating the flame under evaporating basins, etc.; of course a sufficient interval must be kept between the pot and the basin, else the light will be extinguished.

A small flower-pot with wire gauze tied over the top is a very effective low temperature lamp when the gas is lighted below the gauze. If the gas is lighted above the gauze we have a capital argand lamp giving a large, clear blue flame. In the latter case a common burner can be used, a consideration when Bunsen's are all temporarily occupied or not available. After a time the pots become cracked from the heat, but as they are easily replaced this does not matter, and even when cracked they will often hold out for a considerable time. Fireclay flower-pots made rather thick would, however, afford a really good and cheap portable furnace.

By placing the flower-pot inside another just large enough to encase it, loss of heat by radiation would be effectually checked.

To Pulverize Shellac.—Any one who has tried to pound up shellac in a mortar knows that the attempt is more favorable to perspiration and profanity than to the pulverization of the slippery stuff. A correspondent of the *Druggists' Circular* has devised the following method: "Enclose the shellac in a strong, closely-woven piece of cloth, at first compressing the folds rather tightly, but gradually relaxing them. Then, after placing the bunch, which must be held in position with the hand, upon a solid block or smooth counter, the strokes of a heavy iron pestle are applied, gently at first, while the bunch is kept mov ng from side to side, so as to expose every part to the strokes of the pestle. After the large, sharp pieces are broken, the strokes are increased in velocity and power, with wonderful effect upon the resin, and but little injury to the cloth. In this way shellac may be reduced to a granular form sufficiently fine for pyrotechnic purposes at very short notice, and to an almost impalpable powder in a comparatively short space of time. To produce this result, however, it is necessary to wield the pestle forcibly, and then from time to time separate the finer particles from the coarser by sifting."

EXCHANGES.

Wanted, "Butler's Family Aquarium;" will give in exchange two books, entitled "Laughing Gas" and "De Walden's Ball-room Companion." E. R. Brown, Box 25, Covington, Ind.

A small printing press and outfit, cost $12, for steam engine, Demas lathe and scroll saw, or offers. Ernest Corthell, Rockport, Maine.

A patent spectograph, cost when new $1.25; rare minerals, birds' eggs, and postage stamps, to exchange for minerals, foreign coins, Indian relics, or offers. Frank F. Fletcher, St. Johnsbury, Vermont.

Eggs, of the English sparrow, for good specimens of other birds' eggs; botanical specimens mounted and unmounted to exchange; lists exchanged. C. R. Hexamer, New Castle, Westchester Co., N. Y.

Two telegraph instruments, nearly ½ mile of wire, one battery; also 4 in. magnet, 8 Scientific American Supplements, full of information; new history of United States; a $4 German silver-trimmed flute; what offers? Ewing McLean, Greencastle, Ind.

Wanted, The Workshop Companion; I have Gaskell's Compendium, $1; The Round-of-Months, 75c.; Amateur's Hand Book, 15c.; also books, papers, pictures, etc.; send lists of what you have to exchange. W. B. Moore, Morgan Station, Ky.

McAllister's magic lantern and 30 pictures (cost over $95), to exchange for job type and material, or a good microscope and specimens; $20 worth of novels for a good $15 or $20 household microscope; rare mineral and Indian relics for exchange or sale; refers to editor. John T. Patrick Wadesboro, N. C.

What is offered for one of the Climax extension step ladders? H. E. Phelps, Manhall, Michigan.

Wanted, a good microscope in exchange for a scroll saw; instrument must be in good order, and magnifying power of from 200 to 300, or 400 diameters. H. E. Rhodes, Brighton, Iowa.

To exchange, a $3 microscope for some old issues of Canada postage stamps. Wallace Ross, Lock Box 97, Rutland, Vt.

Wanted, a printing press; have for exchange a good microscope (Smith & Beck, London), 3 object glasses, and three eye pieces, power from 15 to 600 diameters, original cost $60; books, chemicals guitars, and other things for exchange. E. F. Underwood, 9 Murray St., N. Y.

Wanted to exchange, Colorado minerals, such as jasper, smoky quartz, silicified wood, etc., for good specimen fossils, or perfect crystals of minerals of other localities. H. F. Wegener, Denver, Colorado.

One Natural Philosophy, one Bryant & Stratton's Counting-house Book, and two long bows, with arrows, to exchange for cabinet specimens or curiosities. W. D. Wright, Lock Box 17, Bremen, Indiana.

Wanted, coins, minerals, and type; send lists of what you have and what is wanted in exchange. A. Campbell, Derrick City, McKean Co., Pa.

An Excelsior Printing Press, with equipments, comparatively new, cost over $47, for double barrel breech-loading shot gun, with reloading tools and shells. William A. Hervey, Box 134, Taunton, Mass.

To exchange, 400 stamps, all different, in a stamp album, for a small printing press with type, etc. Arthur D. McGerald, 106 Bird Ave., Buffalo, New York.

Revolver, microscope, microphone, 4 magnets, skates, skate sharpener, copying pad, books, magazines, $7 worth of rosettes, and lots of other things to exchange; I will give you a better trade than anyone else can. Chas. T. Conover, Esperance, Scho. Co., N. Y.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Photographs of ten of the most influential Indians of Spotted Tail Agency, including Spotted Tail and family and four oil chromos, very beautiful, for printing press, scroll saw, or offers. Luther Emerson, Creighton, Knox Co., Neb.

"Appleton's Picturesque America," never been read or handled, value $24; "Dana's Mineralogy," $10, and coins, to exchange for a breech-loading shot gun, Winchester or Evan's rifle, or offers. D. M. Fuller, Box 115, Camden, Maine.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

One pair best steel climbing irons, handsome seven shot, 22 calibre revolver, full nickel plate, ten dollars worth of boys' papers, and magazines, for works on natural sciences or offers. W. M. Stribling, Circleville, Pickaway Co., Ohio.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho.

Dumb bells of all sizes, to exchange for most any thing; send for circular containing weights of them to J. P. Donohue, Box 7, Davenport, Iowa.

Wanted, scientific books and papers, microscope, drawing instruments, telephone, stamps and coins, in exchange for scroll saw, type, cards, revolver, shot gun, magazines, scientific books, or almost anything. W. L. Goodsell, Bath, N. Y.

A pair of New York Club skates, worth $3.50, also coins, minerals and postage stamps, for books or offers; correspondence invited. E. F. Greene, P. O. Box 889, Bath, Steuben Co., N. Y.

A nice marine oil painting, ready framed, worth $5.00; state what is offered in exchange. C. Hammond, Artist, P. O. Box 47, Chatham, Barnstable Co., Mass.

Photographic camera, one portrait and one landscape tube, with chemicals complete, in exchange for medical books. J. Frederick Herbert, 1,324 Poplar St., Philadelphia, Penn.

What offers for 1 Household Microscope, one 8 shot breech-loading carbine, 1 new 7 shot pistol and cartridges, 1 small gold watch, 1 small gold chain, 1 violin and case, one new darning machine. Lock Box 147, Tarboro, Edgecombe Co., N. C.

Back Nos. "Penman's Art Journal" for 1879; Gaskell's Compendium, $1; Coe & Shells' Pen and Ink Drawing, 25c.; Pettengill's Fortune Teller, 40c.; Hand-Book of Business, 25c.; in exchange for microscope, printing press, or offers. M. B. Moore, Morgan Station, Ky.

Trump's and Russel's scroll patterns, worth $10; for large lenses preferred. H. J. Peters, Rogersville, Ohio.

Lessons in Standard Phonography given in exchange for a printing press, lathe, scroll saw, scientific books, hammock, or offers. Phonographer, Box 331, Topeka, Kans.

Wanted, chemical apparatus, in exchange for "Phrenological Journal," $2, and the last six numbers of "American Agriculturist," 75 cents, of 1879. T. P. Potts, Canonsburg, Pa.

Land and fresh water shells, birds eggs, minerals, fossils (correctly named) or books, Gray's "How Plants Grow," Pope's "Linear Perspective Drawing," in exchange for a Multum in Parvo

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

INDUSTRIAL PUBLICATI

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, JULY, 1880. No. 7.

A Snapper's Home.

BY A. W. ROBERTS.

WITH the assistance of a companion, I had constructed a pond in one of the sunken lots that adjoined the old homestead. The bottom of this pond was puddled with clay to make it as near water tight as possible. The margins were ornamented with masses of rock, with here and there patches of pond lilies, sweet flag, and cat-tail. Near the centre was an island, which went by the name of the "Snappers' Home." It was a pretty spot, built up of odd-shaped stumps of trees and rocks, the spaces between them being filled in with the richest of black peat, in which ferns, lilies, and semi-aquatic plants were planted. This pond was stocked with gold fish and all the various kinds of reptiles that could be procured, and, boy like, those animals that made the most noise were our favorites.

To the south of where now is situated Myrtle Avenue Park, Brooklyn, at the time this pond was constructed, existed a large swamp that teemed with animal life. It had been an unusually hot summer, and the ponds for miles around were drying up, causing the turtles, frogs, snakes, and aquatic insects to leave them and take up their quarters in this remaining piece of water, so that if the dry spell lasted, and this swamp dried down to the "last ditch," things would become very lively. Anxiously I watched and waited each day, the water becoming lower and lower, and thicker from being constantly stirred up by the thousands of distracted animals.

At last, when the water was reduced to a comparatively small space in the lower part of the swamp, I determined to make my first haul. Provided with a bag into which the frogs were to be imprisoned, and a long-handled scap net to capture them with, I reached the swamp an hour after daybreak; at this time of the day the

frogs were mostly on the margin of the swamp, and easy to capture, so that I soon had all the bag would hold.

When resting, before starting for home, my attention was attracted to the pond by a large black and pointed object moving irregularly about upon the surface of the water—forward, sidewise, backward, then disappearing, only to reappear at the lower end of the pond, and so it kept on restlessly moving about. I could stand it no longer; so taking off my shoes and tying the bottoms of my pants over the tops of my stockings—for the horse leeches and boat flies had got to be mighty thick in the water the last few days—I started in search of this new wonder. Taking advantage of the bushes that margined the pond, that my approach might not be observed, I got within a hundred yards of the mysterious object; entering the water I began to move slowly and silently towards it, when it went under. Instantly I dashed to the spot from whence it had disappeared, judging that so large an animal as this must be would leave a trail or track behind it from stirring up the muddy bottom; in this I was correct, for extending from the place where I had last seen him, stretched a broad black and peaty track. Following this rapidly, I soon had the pleasure of knowing that I stood directly over the moving object, but I didn't dare grab it when under the water, not knowing either its size or nature. Presently it ceased moving, and on the surface appeared a small black and pointed object, with two small holes in it; in an instant it disappeared under the surface, and began moving along the bottom very rapidly, stirring up great clouds of peat. It had scented me and was alarmed. I still followed it closely, till it paused once more, and moving to leeward of it I scrouged down close to the surface of the water that it might not scent or see me. Again the small black speck appeared, gradually protruding upward from the surface, higher and higher, till it extended some six inches, and moving cautiously around, it reconnoitered the entire pond with its small, villianous-looking black eyes. For a few minutes we each remained motionless, and after a careful inspection I concluded that I was on the track of one of the most powerful, active, cunning, and wicked of all reptiles that inhabit fresh water, the *Chelydra serpentina*, or "snapper."

There was only one way to capture him, and that was to seize him when under water; a rather dangerous proceeding, for if he once closed his powerful jaws on me nothing would cause him to lose his hold (absurd as it may seem, it is nevertheless true that the head of this turtle, after being cut off, will retain sufficient vitality to maintain a firm hold upon the object seized for several hours). Knowing, by the young specimens of this variety of turtle that I had kept in aquaria, that when in motion their tails dragged behind them, and that if I could find exactly the position of this fellow's tail, and once get a good hold of it with both hands, I could pull him to the shore and thus secure him for my pond. Following in his wake once more, I cautiously felt for his tail with my foot, not liking to give him a chance at my arms or hands in case we came to close quarters. The water being thick, he could not see my foot, and I touched him so carefully and lightly that he paid no attention to me. His tail seemed to be enormous, and of a rough horny texture, extending a considerable distance out from his shell. Seizing him with both hands, I was dragging him towards the shore, as I did not dare lift him out of the water, not knowing his weight and fearing he might turn on me, when he fastened on an old root with his fore feet and held fast. I braced back, and was pulling with all my might, when he let go his hold, and, my feet slipping from under me, we both lay sprawling and splashing in the water. In an instant I regained my feet, still holding on to his tail, and gaining the shore, dragged him to a newly-plowed field, where I knew he could not get away from me. When I let go of him he rose up on his four feet and lunged at me, at the same time opening his mouth and snapping at me savagely with his sharp jaws. He was a very fine specimen, and weighed some twenty pounds.

My next anxiety was to secure him so that I might take him home for the pond.

I did not dare approach him, he being so watchful and quick in his motions. At last I bethought me to cover him over with sod and stones; this took me some time to accomplish. Then taking off my suspenders, and making a slip noose at the end of them, I proceeded to dig down through the sod till I reached one of his hind legs, to which I secured the suspenders, by which I dragged him to the nearest farmhouse, when I fastened him in a large box, and arranged with the farmer to deliver him to me next day.

When he was placed in the pond he took immediate possession of the island, remaining there all the season. To prevent his foraging on the inhabitants of the pond I fed him bountifully on raw beef, with now and then a fish or dead frog, also the stems of water lilies, of which he seemed very fond; still I think he never felt happy, as he had a way of making a subdued and smothered bellowing noise, as if calling for his mate. From this swamp I stocked my pond with hundreds of frogs, lizards, aquatic insects, and their larvæ.

The young of the snapping turtle, if very small, is one of the most interesting of all the reptiles for an aquarium, but he must be fed *regularly* and *bountifully*. In course of time he will learn to feed from your hand, and will allow you to take him out of the water and handle him. I have had them so tame that they would sit in the palm of my hand and feed, tearing the food in pieces with their sharp claws. When young the shell is very soft, but in a few months begins to harden.

The female snapping turtle deposits her eggs about the latter part of May, some distance from the shore, where she digs a deep hole in the sand or loose earth with her powerful fore feet. All the eggs are deposited at one laying, and are covered over with loose earth, dry leaves, and grass, and are left to hatch out as best they can. Skunks and weasels are particularly fond of turtle eggs, and devour large quantities of them. The young take to the shallow water as soon as free from the egg, feeding on aquatic insects and larvæ, to which they are very partial.

Prof. Agassiz says, in his "Contribution to the Natural History of the United States": "The snapping turtle exhibits its ferocious nature even before it leaves the egg; before it breathes through lungs; before its derm is ossified to form a bony shield; nay, it snaps with its gaping jaws at anything brought near. Though it be still surrounded with amnion and allantois, and the yolk still exceeds in bulk its whole body, I have seen it snapping in the same fierce manner as it does when full grown, at a time when it was a pale, almost colorless embryo, wrapped in its fœtal envelope—three months before hatching."

The snapper is a long-lived animal, their growth continuing during the entire period of their existence. Snapping turtles used to be quite plentiful, but are now becoming more scarce every year, from the fact that large numbers of the young are taken every year by collectors for aquaria. And the large-sized ones are sold to fish dealers, from whom they are purchased for the purpose of making "terrapin soup."

Next to a snapping turtle, for an aquarium, is the beautiful "painted turtle" (*Chrysemys picta*), which is still abundant in all ponds and ditches. It has none of the ferocious nature of the snapper, but is of a mild and timid nature, easily petted, very active and inquisitive, and an excellent swimmer. I have had them so tame that they would come to be fed at my call, allowing me to handle them freely, and seeming to be delighted when I gave them a hot sun bath. The name of painted tortoise is derived from the fact of its shell being ornamented with such rich and intense contrasts of color. The margins of the under shell and legs being loaded with a deep rich vermilion color and olive brown. Its head having bright yellow markings along the sides, and the plates of the upper shell being slightly margined with a dull yellow. This and the young of the snapper are the only two kinds of turtle that I can recommend for fresh-water aquaria, but they must always be very small. All dealers keep them in stock. The spotted or mud turtle, and musk or stinking turtle are inactive, and, refusing food, soon die. When turtles are

kept in aquaria, the rock work should extend well above the surface of the water, and in that part of the tank that receives the most sunlight, so that they can rest and bask at their pleasure. The best food for turtles is plenty of lean beef. A good way is to hang a small piece in one corner of the tank so that they can help themselves; if well fed they will not molest the fish.

A Home-Made Bouquet Holder.

THE pretty little bouquet holder which we have figured in the accompanying engraving, is made out of very common materials, and requires no great skill nor any elaborate tools. The holder itself is merely one of those glass balls which marksmen employ for shooting at, and the base is a wooden cup, which any smart boy that has one of the common little cheap lathes will find no difficulty in making. A sound piece of beech or maple, large enough to make the base, should be screwed on to the spindle of the

BOUQUET HOLDER.

lathe and roughly turned up to shape. The cup is then turned out and finished smoothly inside, after which the outside is turned to the exact size and carefully finished and polished. The polishing is done in the lathe, and is quite easy, as the high speed that we can give to the wood makes it polish very easily. A little good shellac varnish is the best material.

The mouth of the holder is also turned out of wood, or it may be fashioned out of sealing wax. If the ball be gradually heated until it is warm enough to melt the wax, the latter will adhere quite firmly, and may be easily moulded by the fingers into any shape.

If the upper edge of the wooden cup is scalloped, as shown in the figure, its appearance is greatly improved. The scalloping is readily done by means of a penknife. While the cup is in the lathe, make a very light mark on the inside, and as far from the edge as the scallops are to be deep. Then mark the scallops out carefully with a pencil, and cut them with a penknife. The edge may be finished with a fine file and the very finest sandpaper.

Glass Engraving.

BY A. G. M'KEAN.

ONE of the most interesting and useful operations with the foot lathe, is that of engraving on glass. The tools required, beside the lathe, are few and inexpensive, comprising several sizes of copper wheels, from 1-32 inch to 1-2 inch in thickness, and from 1-8 inch to 3 inches in diameter. A great variety of work may be done with these sizes, but the larger the assortment the better. They should be attached to the lathe spindles in any convenient manner, but it is best to attach the larger sizes by means of a screw thread, and the smaller sizes by means of a chuck.

The periphery of some of the wheels may be beveled, some rounded, and some made square across.

When all is ready, apply some flour of emery, mixed with a little olive oil, to the periphery of the wheel, and at the same time revolve it slowly. Now bring the glass in contact with the wheel, when it will be found to cut. Should the wheel cease to cut, apply more of the oil and emery.

In engraving letters, the letter to be engraved should be laid on the glass with a mixture of gum-water and whiting, by means of a pen or camels-hair brush.

The amateur must learn, by experience, which wheels to use, the larger ones being used for straight lines and large curves, and the smaller ones for small curves. It will surprise the amateur how quickly

and easily one may acquire proficiency in the art.

Precious stones are cut in the same way, except an iron wheel is used instead of a copper one, and diamond dust instead of flour of emery.

Fern Pictures.

A SIMPLE photographic method of making fern pictures is thus described by the *Chemist and Druggist:* Cover a sheet of paper with a weak solution of salt in water and some white of an egg, well beaten; after it is dry, take it into a dark room, and with a tuft of cotton pass over it a solution of nitrate of silver (50 grains to an ounce of water); dry it in the dark, and the coat of chloride of silver formed on its surface will receive the impression. Then arrange your ferns between two plates of glass, and cut the paper to the same size as the glass plates; place it under them and expose to the sun, in the same way as a photographer prints a portrait. Watch it until dark enough, and before removing the paper from the glass take it into a dark room. Here place the picture in a solution of hyposulphite of soda, which will dissolve the chloride of silver, but leave the decomposed material (finely divided black silver) which forms the black background, while the shadow of the leaves will be white.

The old method of *spray* or *spatter* work also gives very good results: Take a sheet of strong white paper, and with an atomizer pass over it a spray of very diluted mucilage, so as to obtain a very thin and slightly sticking film, which will make the ferns adhere of which it is desired to make the picture. The ferns and leaves must have been first pressed in a book, and after arranging them to suit your taste, cause them to lie as closely to the paper as possible; fill an atomizer with very diluted India ink, and blow a spray over the ferns, more or less in proportion as you want a darker or lighter shade. It is well to do this with intermissions, letting it dry a little, so as to avoid excess of moisture and possibility of running the liquid into drops. When nearly dry, but still a little moist, remove the ferns, which may be used over again several times, each time being arranged in different figures. Instead of causing them to stick with mucilage, however, it is best to fasten the ferns to the paper lightly with fine pins. The figure of the fern is left white on a grey ground, and the figure of the fern leaves may be greatly improved by veining them with a pencil.

For an atomizer use either the old plan of a brush drawn across a sharp edge, or over a piece of wire netting, such as a coal sieve, or use the method described in a fomer number of this journal.

Home-Made Telescopes and Microscopes.—VII.

ON THE PRODUCTION OF SPHERICAL SURFACES IN GLASS.

HAVING got our lens perfectly smoothed and figured, the next operation is the polishing. It is almost impracticable to perform this in the hard mould, and therefore various substances are employed of a less degree of hardness, in which the coarser particles of polishing powder may become imbedded. 1. For the larger sized lenses in microscope work, beeswax, hardened with some resin and finely-washed ochre, is very suitable, but for medium sizes this is too soft and yielding. 2. A mixture of shellac and washed putty-powder is therefore employed, which is very enduring. These are melted together and stirred diligently; the shellac is added until the whole arrives at the consistence of thick paste; and as the lac is apt to burn, to prevent this a lump of beeswax should be thrown into the mass. This does not actually mix with the other ingredients, but lessens the risk of spoiling the composition by overheating; when cool enough the mass may be rolled into sticks between two greased boards.

For the very smallest lenses, such as the fronts of a 1-25th and a 1-50th, the last composition is still too soft and fragile to maintain a true figure. The polishing mould is therefore, for these, made in the end of a rod of pure tin, which is cut out

into a nearly hemispherical cup by the appropriate steel gauge; the "pip" is removed with a needle-point.

The wax-polishing bed is turned out to the required radius, and finished by scraping with the steel gauge; but as the material is somewhat yielding, the lens soon plays to the mould and keeps its figure during the polishing.

The second composition is very hard and brittle, and does not yield at all, and as the body is composed of the hard oxide of tin, this would speedily injure the gauges if used as cutting tools. The method that I have adopted for forming the polishing moulds from this substance is as follows:—A lump of the material is fastened by heat into a ferrule, or hollow cup, running in the lathe; the end is then turned either convex or concave, and of a diameter suitable for the lens to be polished; the convex or concave mould, as required (which has been worked off at last near to a polish, as before explained), is then screwed on to a handle, and held in a flame till, when touched with the moistened finger, it hisses smartly; a morsel of tallow is then put on the rough-turned composition to prevent adhesion, and the hot mould worked and rotated over it in every direction till cold; when removed the polisher will have taken the exact form of the heated mould, and have acquired a fine polish. For either convex or concave lenses the "pip" is taken out as usual, and it is advisable to make a few concentric scratches in the polisher if of large diameter.

As the mixture of crocus and putty-powder, recommended for polishing, is apt to cling in these moulds if applied at once, I first use the putty-powder alone; this cleans the hard polish off the face, and the operation may then be continued with the mixture.

One great advantage of this composition for a polishing mould is the decided way in which it maintains a true figure; for, unlike any other of the kind, it undergoes a very slight degree of wear, so that the face is always kept clean; and any number of lenses of similar form and radius may be polished in the same tool without having to alter or mend the figure, and perfect accuracy is the result. The composition is now generally known, but Mr. James Smith is the original discoverer of it. For the last degree of polish I sometimes rub a thin layer of pure soft beeswax in the mould, and smooth it down to form with the now finished lens; then a small quantity of the very finest washed crocus is applied, and the lens worked therein for about one minute. The extra brilliancy of surface obtained in this way is quite appreciable and well worth the pains bestowed, as the operation is not continued long enough to run the risk of injuring the figure.

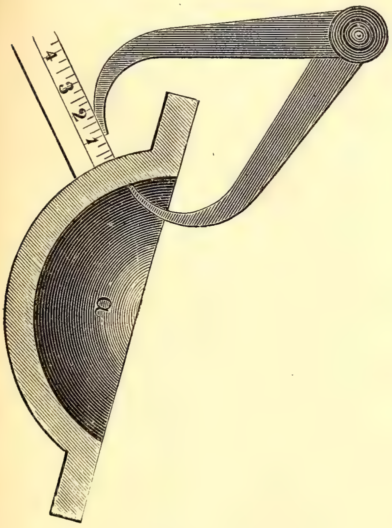
I have now only to give some directions for cementing the lenses together. The surfaces having been carefully cleaned, the two lenses are laid on a hot plate; a drop of Canada balsam is placed in the concave, the group of bubbles thrown up by the heat removed by a brass point; with this the convex lens (which is equally hot with the other) is lowered slantways into the balsam so as to avoid bubbles, and the two lenses are pressed together; they are now lifted off the plate with a pair of curved forceps held nearly horizontally, and shifted one-quarter round, and then dropped down again. This is repeated a number of times, and the two lenses being exactly of the same diameter, this operation must set them concentric as a matter of course. If the lens is a triple, the opposite surface of the concave must be cleaned, and the balsam removed with strong alcohol (turpentine must not be used as it percolates the balsam too easily, and is apt to cause bubbles to appear at the edges), and the same operation repeated as on the other side. When the lens is cleaned with alcohol, and examined edgeways with a magnifier, the three lenses will appear quite concentric, and should just pass into the cell without requiring any force; and if the workmanship has been correct—viz., all the cells turned true from one chucking, and the concaves of equal thickness and concentric with their respective convex lenses, no errors of centering can occur. The usual way of correcting this is by tilting the lenses in the cells in which they are

cemented with Canada balsam; but at the best this is only to some extent substituting one error for another.

Measuring Inaccessible Dimensions.

THE following ingenious "wrinkle," which we find in the *Millstone*, is by Mr. John Walker, of Baltimore, and will frequently prove useful to amateur mechanics. It is remarkable for its simplicity and the common want it so readily and accurately supplies. The practical mechanic is frequently at his wit's end to find dimensions in peculiarly difficult places, which no tool he may possess is fitted to determine.

The following illustration will serve to show how simple a thing it is to get the dimensions of any piece of work in whatever shape it may be. The casting in this



A NEW WAY TO MEASURE.

case being of spherical form, with flange, it would puzzle most mechanics without special tools to find its thickness. The first thing usually resorted to would be to drill a hole at a designated point. The above wrinkle provides a readier method, and does away with the application of special tools. By simply applying a common rule, as shown, and setting the caliper to some even inch on the rule, so that it may easily be removed, it will be seen that the difference between the even inch denoted and the actual opening of the caliper is the dimension required.

Bleaching and Dyeing Bone and Ivory.

IVORY is so frequently used by the amateur workman, and enters into the formation of so many instruments, that a good method of bleaching it is of great value.

M. Cloez being consulted by M. Gratiolet on the best way of removing the yellowish and fatty appearance of skeletons, as well as their unpleasant odor, advised the use of the solvents for fatty bodies, and especially the oil of turpentine. He was surprised to see not merely that the cadaverous odor disappeared in a short time, but that the bones became of a dazzling whiteness.

The same process applied to ivory gave a perfect bleaching. An exposure of three or four days to the sun in oil of turpentine is quite sufficient. An essential precaution is to support the objects to be bleached upon little supports of zinc, so that they may be raised a few millimetres above the bottom of the glass vessel in which they are placed.

Oil of turpentine is, in fact, a very powerful oxidizing agent, and it acts by reason of this property; the product of the reaction forms an acid liquid, which spreads on the bottom of the vessel in a shallow layer, and if the objects to be bleached dip into this acid liquid they become attacked.

The action of the oil is not only exerted on bone and ivory—it acts also upon woods and other bodies. Beech, maple, elm, yield excellent results, and cork is whitened very rapidly. Oil of turpentine is not the only one which possesses these properties; oil of citron and the other isomeric oils possess the same effect.

Ivory is easily dyed in different colors, but in order that the dye may be fast, the articles to be dyed should be previously steeped from six to eight hours in vinegar, or better, in a solution of alum. They may then be dyed a fine red by a decoction of Brazil wood; yellow with saffron

(!) or barberries; green with a mixture of three parts verdigris and one part sal-ammoniac dissolved in vinegar; and a fine blue by steeping them alternately in the above green bath and in potash lye. Black is obtained by alternate baths of logwood and black liquor.—*Moniteur de la Teinture.*

Gems and Precious Stones.

GEMS and precious stones always excite interest, not only from their great value, but on account of their exceeding beauty and the deep scientific interest which attaches to them. It is a wonderful fact that the diamond has almost exactly the same chemical constitution as the black lead which we use in our pencils, and the ruby and sapphire are merely pure alumina—an earth which forms a very large proportion of the soil which we till, and which, when out of place, we call dirt. A few words in regard to the principal gems may therefore please our young readers.

The *Diamond* is the hardest known substance, and one of the most unalterable gems. It is not affected by chemicals, is infusible, only to be consumed by exposure to a long-continued or very high temperature; and these qualities, combined with its rare brilliancy, make it the most valuable of precious stones. It is pure carbon ; chemically almost the same as graphite, or plumbago, and charcoal ; but very different from them in its transparency and lustre. It is generally found in octahedral crystals, having highly polished faces; and although possessing some beauty in this natural state, owing to the high lustre of the faces, yet it has not a tithe of the splendor exhibited by a well-cut brilliant. The ancients did not know how to cut the extremely hard diamond, and were content to wear it in its natural state, but even thus they prized it highly.

According to their transparency and lustre, diamonds are classified into stones of the first water, second water, and refuse stones. To be the first water a diamond must be absolutely colorless, very lustrous, and perfectly free from flaws. An undecided tint of any color injures its value; and although deep red, green, or blue hues may give the stones an exceptional value as fancy specimens, yet in the ordinary market they would be much less esteemed. A yellow tint always depreciates the value; and on this account many of the stones so recently found in South Africa bring very low prices. These African stones, moreover, lack the perfect lustre of Brazilian diamonds, and have, in consequence, commanded far lower prices.

A well-cut diamond, of the first water, is at present worth in New York about $50 gold, if it weighs half a carat (the carat being four grains Troy); if weighing one carat, $175; if two carats, $550. Above this weight the values depend on very delicate shades of difference. One stone of three carats may bring $800, another might be worth $1,000. Above three carats the price is only settled by agreement. A diamond of five carats is a very large stone, and above one hundred carats few are known.

Diamonds are found in alluvial deposits, from which they are separated by washing. In Brazil the work is done by slaves, and the fortunate finder of a stone of over seventeen carats receives his freedom and a suit of clothes. Scarcely one in ten thousand is found to weigh so much, and the majority of them weigh but a very small fraction of a carat.

The most celebrated localities in ancient times were Golconda and Borneo; but in 1727 the diggings in Brazil were opened, and yielded so abundantly as to greatly depreciate the value of diamonds, and the dealers tried to make people believe that they were not true diamonds. Lately diamonds have been found in Australia and South Africa, and a few in North Carolina, Virginia, and California; but Brazil furnishes the most abundant supplies and the best gems.

In our next article we shall tell our readers something about rubies and sapphires.

— The best rock-work for aquaria might be made of clay, such as is used for terra cotta, moulded to the required form, and baked quite hard, but not glazed. It might be colored of any tint before being baked.

THE MOON, IV.

The Alps (80); a lofty and very steep chain rising into separate peaks; one of the highest is Mount Blanc (next to which the number on the map stands)—rises more than 13,000 feet. It is always easily found. Cassini (81) is a very curious ring-plain, having narrow walls and casting a long spire of shade in the First Quarter. It contains a small, deep crater. Aristillus (83) is one of the most conspicuous objects to be seen in the moon, and always attracts the eye first. It is a crater 34 miles broad and 11,000 feet deep, with a fine central mountain. The ring is very steep, and is surrounded by radiating banks, resembling lava streams—best seen about one day after First Quarter. South of it is a companion crater (84), nearly as deep and bearing less evidence of a flow of lava. They seem to be connected by low ridges. The Apennines (85) is a very extensive chain, more nearly resembling the mountains of the earth than is generally the case. Its length is 460 miles, running over into the next quadrant. It casts a shadow 83 miles long. Huygens (90) is

its loftiest peak, rising to a height of 21,000 feet, and bearing on its apex a minute crater. Other peaks, though not so high, are, nevertheless, of extraordinary height and steepness: Hadley (87) is 15,000 feet; Bradley (89) is 13,000 feet; and Wolf (92) is 11,000 feet. The gradual entrance of the summits into sunshine, about the First Quarter, is a glorious spectacle, and their projection beyond the darkness, thrusting their high heads through the blackness below, and receiving the golden rays of the sun, give them the appearance of golden islands in a sea of ink, which may be seen by a keen eye, and which probably first gave rise to the idea that the Moon was mountainous. An idea of the abruptness of this range may be formed from the fact that its shadows do not disappear until a few hours before the full. It contains but very few craters, and consists of ridges and peaks. Upon the southwestern border of the Sea of Vapor (L), and passing through the well-known crater Hyginus (93), is the canal of Hyginus, indicated upon the map. It can be seen with a power of 40 under any moderate-sized objective. It begins at the foot of a long low hill, as a flat valley about 1½ miles wide and 9 miles long, contracting to about one half that width, with steep sides and great depth; passes by four minute craters and ploughs its way through the massive walls of Hyginus, and throwing up walls upon either side upon the inside of the crater. Here it bends and begins to grow shallow. It was just north of Hyginus that Dr. Hermann J. Klein, of Koln, discovered a new crater about ten years ago. The discovery was confirmed by all the leading astronomers of Europe and America. Hence, the Moon is not a "dead world," but still liveth, though undoubtedly very near its end.

Penn Yan, N. Y.

Filing Flat and Other Surfaces.

(Concluded from page 75.)

One of the chief obstructions to filing a flat is that the natural action of the hand and elbow are in circular lines. This occurs, as will be seen from the joints of the limbs in action being the centre of motion. It is to overcome this that the careful training of the hands is required to enable a flat surface to be filed. The amateur or mechanic, whichever it is, must be careful in the selection of his file-handles; they should be in proper proportion, not too large and not too small. Now here is a point upon which scarcely two men agree. Some like a large, bulky handle: others prefer a smaller, but one with less curve in it; so this must be left for the operator to suit his own taste. I have many times seen a man take a piece of chisel-rod that happened to be near him, and simply stick the file into it. This is decidedly wrong; it shows a slovenly workman, to begin with, and is exceedingly dangerous, as a file is likely to slip out of such a temporary thing, and if it should do so, the consequences may be most serious. The best description of handles are those made from the softer kinds of wood, and they should have strong iron or brass ferules round the ends into which the tang of the file is driven. The shank or tang of the file is made in a taper form, and should be well fitted into the handle by means of a router, which is made in a similar shape and cut across like a float, which instrument (the float) is used by cabinet-makers. This need not be hardened, as it is only used to cut soft wood. It is made with a shank to hold in the vice, the handle to be cut out is to be held in the hand; a few thrusts to and fro will cut out the inside to the shape of the tang of the file. This done, the shank is then driven into the handle, but not clean up to the end, as if this occurs, the file will be likely to soon drop out of the handle. From this cause we once had a man whose left foot was pinned to the floor by the file, a heavy one, falling straight down out of its handle. This fact induces me to ask all intending vice-men to pay particular attention to the handling of their files. Many other ways have been resorted to, to open the handle to fit the shank, such as making a piece of iron of a corresponding shape red-hot, and burning out the hole. This is bad, as it chars the inside, renders it less likely to wear than anything, and also causes it to slip up all ways. There are also many slovenish ways and means of making shift * * * * Learn to keep your vice clean, and your files in a row neatly arranged, and when taking into use a new set of files, mark one side and reserve the side so denoted for purposes that require an extra sharp edge. Again, have a set of files for different metals. As I have said, when they will not cut brass well, they may be used for iron and steel, and will be quite as good as new ones; but if used upon cast-iron or steel, they will be of no use whatever for brass. In cast-iron especially the scale is fatal to a good file, therefore, see that the sand and rough parts are well rubbed off with any old worn-out file. There are many different ways of finishing vice-work; some draw-file a long piece, which is done by placing the file across the work at right angles, and with both hands draw it backwards and forwards. Much practice is required to do this effectually, and if not properly done, the marks left from the file, instead of being in a straight line, will be across the corners, and when finishing work it is a troublesome job to

get rid of them. The finishing or polishing of all vice-work is a matter that requires patience. Here, again, many methods are employed, such as emery sticks, emery cloth, emery paper, etc. The best plan I have always found, during some years experience, and the same I now adopt, is to fold round a suitable-sized file a piece of good emery paper. If this is nicely done, the surface will be as flat as that of a file, and the process of polishing will not round off the edges. This is a most important point in finishing good work. When the polished surfaces present a rounded appearance, it creates a great impression that it is either of inferior quality, or else some second-hand work that has been got up several times. The finish of good work goes a long way to establish its superiority. Another point must be well looked to, and that is, be particular not to have a high polish and deep scratches. In some cases the glare produced by high polish becomes to the uninitiated paramount to a finish, but the enlightened and educated mechanic will view this with disdain similar to that shown by a West End jeweller on examining articles composed of Abyssinian gold.

In these few remarks enough has been said respecting the method of holding, filing, and the getting up of a flat surface, so far as they refer to that alone. I allude principally to work that requires such high finish as described. For ordinary work, draw-filing, when well done, is generally considered sufficient, and I must say I duly appreciate *such when it is perfect.* Having gone so far, before proceeding to describe the manner in which other branches of this interesting work are executed—such as curved lines, square and mortice holes, etc.—I think a hint as to cleaning the files will be deemed necessary. A very general practice is to use what is called a file-card. This is similar to a scratch-brush, and is composed of a piece of flat carding nailed to a block of wood, and when used, should be in a transverse direction across the file. But beyond the ordinary metal that will accumulate in the file, thereby clogging, sometimes, or rather very often, it will become full of what are termed "pins;" that is, small pieces will firmly wedge themselves into the teeth, and do much damage to the work, in as much as they cut out deep lines, which will take a deal of time to eradicate. This often occurs from working the file quite dry, especially a smooth one, and it may be avoided by using a little oil or chalk. Either of these additions will make it cut several degrees smoother. However, we will assume that the file has become filled with these so-called " pins," and all the persuasion possible will not induce the card to remove them. The best plan I have always found is to have at hand a small piece of sheet brass or tin, beaten out at one end, and with this they may be easily disposed of, by manipulating it in the same transverse direction as the file card, except that instead of brushing, as it were, you simply push out the pins, without doing any damage to the file. We now come to a different description of work to be executed with the file, and I do not think we can do better than take for our example curved lines, although many such are now done in shaping-machines, which useful articles, by the way, have reduced the maximum of skilled vice-men; at the same time, an efficient workman must be capable of executing any shape that may be required. In the production of the various mouldings, etc., that are likely to be required, a number of different files will be requisite, such as crossing, rat-tail, half-round, pillar, warding, and many others too numerous to be detailed. The great thing to practice is the movement of the wrist; nothing but experience will enable a vice-man to show perfect work of this description. When making a shape, say an ogee-moulding tool, which tool may be required to produce a quantity of work from it all exactly alike, the hollow part must be taken out with a half-round or a crossing file, which will depend upon the curve and the opposite curve with a narrow pillar file. Possibly to a person that has had some experience—and it is scarcely what a novice would undertake—this would not be found a very difficult task; but having make the one to his satisfaction, let him now make the reverse tool to fit it exactly, without showing light through it when held to the daylight. When this can be done, the person who succeeds in so doing will not require any more of my limited brains to tell him how to proceed with a course of instruction in which he must be well versed. As to the various shapes to be produced, I will not attempt to enumerate them, suffice to say that I have made myself, in tools of this kind, some six or seven dozens of different shapes.—*Forge and Lathe.*

One Cause of Bathing Accidents.

The *London Lancet* gives the following very excellent caution to bathers: "It is very generally believed that the proper way to bathe is to take a header into the sea, or, at least, to immerse the whole body immediately. Theoretically this may be done, so far as the most vigorous organisms are concerned, but it must not be forgotten that a man may be perfectly healthy, and yet not endowed with sufficient latent energy to recover quickly from the 'shock' which must in all cases be inflicted on

the nerve-centres, by suddenly plunging the whole surface of the skin, with its terminal nervous twigs, into a cold bath. For a time, at least, the central activity must be reduced in force, if not in form. When, therefore, a man plunges, and immediately after strikes out to swim, it is not only possible, but probable, that he may become exhausted, and fail from depression of energy, with cramp. It is important that this should be noticed. We do not think sufficient attention has yet been given to this cause of 'accident' in bathing. Cases of exhaustion from remaining too long in the water with a full stomach are understood. That to which we have adverted is not recognised."

EXCHANGES.

Wanted, "Butler's Family Aquarium;" will give in exchange two books, entitled "Laughing Gas" and "De Walden's Ball-room Companion." E. R. Brown, Box 25, Covington, Ind.

A small printing press and outfit, cost $12, for steam engine, Demas lathe and scroll saw, or offers. Ernest Corthell, Rockport, Maine.

A patent spectograph, cost when new $1.25; rare minerals, birds' eggs, and postage stamps, to exchange for minerals, foreign coins, Indian relics, or offers. Frank F. Fletcher, St. Johnsbury, Vermont.

Eggs, of the English sparrow, for good specimens of other birds' eggs; botanical specimens mounted and unmounted to exchange; lists exchanged. C. R. Hexamer, New Castle, Westchester Co., N. Y.

Two telegraph instruments, nearly ½ mile of wire, one battery; also 4 in. magnet, 8 Scientific American Supplements, full of information; new history of United States; a $4 German silver-trimmed flute; what offers? Ewing McLean, Greencastle, Ind.

Wanted, The Workshop Companion; I have Gaskell's Compendium, $1; The Round-of-Months, 75c.; Amateur's Hand Book, 15c.; also books, papers, pictures, etc.; send lists of what you have to exchange. W. B. Moore, Morgan Station, Ky.

McAllister's magic lantern and 30 pictures (cost over $95), to exchange for job type and material, or a good microscope and specimens; $20 worth of novels for a good $15 or $20 household microscope; rare mineral and Indian relics for exchange or sale; refers to editor. John T. Patrick, Wadesboro, N. C.

What is offered for one of the Climax extension step ladders? H. E. Phelps, Manhall, Michigan.

Wanted, a good microscope in exchange for a scroll saw; instrument must be in good order, and magnifying power of from 200 to 300, or 400 diameters. H. E. Rhodes, Brighton, Iowa.

To exchange, a $3 microscope for some old issues of Canada postage stamps. Wallace Ross, Lock Box 97, Rutland, Vt.

Wanted, a printing press; have for exchange a good microscope (Smith & Beck, London), 3 object glasses, and three eye pieces, power from 15 to 600 diameters, original cost $60; books, chemicals, guitars, and other things for exchange. E. F. Underwood, 9 Murray St., N. Y.

Wanted to exchange, Colorado minerals, such as jasper, smoky quartz, silicified wood, etc., for good specimen fossils, or perfect crystals of minerals of other localities. H. F. Wegener, Denver, Colorado.

One Natural Philosophy, one Bryant & Stratton's Counting-house Book, and two long bows, with arrows, to exchange for cabinet specimens or curiosities. W. D. Wright, Lock Box 17, Bremen, Indiana.

Wanted, coins, minerals, and type; send lists of what you have and what is wanted in exchange. A. Campbell, Derrick City, McKean Co., Pa.

An Excelsior Printing Press, with equipments, comparatively new, cost over $47, for double barrel breech-loading shot gun, with reloading tools and shells. William A. Hervey, Box 134, Taunton, Mass.

To exchange, 400 stamps, all different, in a stamp album, for a small printing press with type, etc. Arthur D. McGerald, 106 Bird Ave., Buffalo, New York.

Revolver, microscope, microphone, 4 magnets, skates, skate sharpener, copying pad, books, magazines, $7 worth of rosettes, and lots of other things to exchange; I will give you a better trade than anyone else can. Chas. T. Conover, Esperance, Scho. Co., N. Y.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Photographs of ten of the most influential Indians of Spotted Tail Agency, including Spotted Tail and family and four oil chromos, very beautiful, for printing press, scroll saw, or offers. Luther Emerson, Creighton, Knox Co., Neb.

"Appleton's Picturesque America," never been read or handled, value $24; "Dana's Mineralogy," $10, and coins, to exchange for a breech-loading shot gun, Winchester or Evan's rifle, or offers. D. M. Fuller, Box 115, Camden, Maine.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

One pair best steel climbing irons, handsome seven shot, 22 calibre revolver, full nickel plate, ten dollars worth of boys' papers, and magazines, for works on natural sciences or offers. W. M. Stribling, Circleville, Pickaway Co., Ohio.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho.

Dumb bells of all sizes, to exchange for most any thing; send for circular containing weights of them to J. P. Donohue, Box 7, Davenport, Iowa.

Wanted, scientific books and papers, microscope, drawing instruments, telephone, stamps and coins, in exchange for scroll saw, type, cards, revolver, shot gun, magazines, scientific books, or almost anything. W. L. Goodsell, Bath, N. Y.

A pair of New York Club skates, worth $3.50, also coins, minerals and postage stamps, for books or offers; correspondence invited. E. F. Greene, P. O. Box 889, Bath, Steuben Co., N. Y.

A nice marine oil painting, ready framed, worth $5.00; state what is offered in exchange. C. Hammond, Artist, P. O. Box 47, Chatham, Barnstable Co., Mass.

Photographic camera, one portrait and one landscape tube, with chemicals complete, in exchange for medical books. J. Frederick Herbert, 1,324 Poplar St., Philadelphia, Penn.

Trump's and Russel's scroll patterns, worth $10; for large lenses preferred. H. J. Peters, Rogersville, Ohio.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

INDUSTRIAL PUBLICAT

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, AUGUST, 1880. No. 8.

How to Learn to Draw.

MANY young people who are anxious to learn the art of drawing in some of its numerous departments cannot procure the assistance of a teacher, and are therefore at a loss to know how to begin. In drawing, as in many other things, it is the first step that is the most difficult, and too often we find young people discouraged and confused because they commence some department for which their natural talents and previous training has not fitted them. It has occurred to us that a few words in regard to the different departments of the subject, and the preliminary studies required, would prove of value to many of our readers.

The art of drawing enables us to represent upon a surface objects which have more or less depth or solidity, and we can thus convey to the mind a correct idea of whatever we wish to represent, whether it be a landscape, a house, a machine or a person. And when the drawing has been accurately made, according to correct rules, it enables us to reproduce exact copies of such subjects as are within the scope of our constructive abilities.

There are several distinct branches of the art, and these several branches require varying degrees of natural talent, and different kinds of preliminary training. The principal divisions are free-hand and instrumental drawing, and each of these has its subordinate but distinct sections. By *free-hand* drawing is meant the production of figures by the hand and pencil alone, without the use of rulers, compasses or other guides, while instrumental drawing allows the use of rulers for straight lines, squares and triangles for setting off angles, and compasses and templates for laying out curves. These two methods, free-hand and instrumental, may be applied either to simple projections or to the most intricate methods. Thus we have *sketching,* in which, by a

free-hand process, the artist gives a representation of any object placed before him and geometrical perspective, in which the lines and distances are measured off and laid down by means of instruments. Some kinds of drawing are named after the special application which is made of them, as map drawing, architectural drawing, machine drawing, etc., and although the principles and rules employed are the same in all, yet skill in any one branch depends very much upon the experience which has been had in it, so that it is not uncommon to find persons who are very skilful in one department, and yet are not very successful in others.

As an extension of the art of drawing, and frequently confounded with it, we have the art of *designing*, in which no actually existing object is figured, the draughtsman relying upon his ideality and imagination for the figures which he produces.

The student will do well to endeavor to acquire clear ideas in regard to the special branch to which he proposes to devote his attention. For practical purposes the different branches of the art may be arranged under three principal heads:

1. *Pure art*, in which, by means of free-hand drawings and sketches, effects are produced which are valuable for their own beauty and interest, but are not necessarily of any use in the industrial arts or in every-day life. Such drawings resemble pictures or engravings—they are kept merely to be looked at, and the degree of skill which is required to produce them of superior excellence, confers upon them a pecuniary value which is sometimes very high. Artists capable of attaining this high degree of excellence are born, not made, and to those who aspire to this department of art, we cannot presume to have anything to say.

2. *Free-hand drawing as applied to the Arts.* This may consist of mere sketching, which gives an idea of the form but not always of the exact size of the different parts of objects. The power to make free-hand sketches is invaluable, as it enables us to note down in a rapid manner things which could never otherwise be committed to paper. It has also a special value in its influence as a means of mental training, since no exercise cultivates the powers and habit of exact observation so thoroughly and so rapidly as the art of drawing. When we see an object we carry away a vague idea of its general form and outlines, and even this we are not *compelled* to do, so that if the mind is in a listless or inattentive mood, we may pass over entirely many of the most important features. When, however, we attempt to make a drawing, we are compelled to attend closely not only to general features, but to details, and the training thus acquired is invaluable. In addition to this is the exercise of transferring to paper the ideas thus acquired. This involves the accurate measurement of distances and the correct estimation of direction and form, as well as of color, shade, etc.

3. *Design.* Those who by native skill and judicious training have acquired a high degree of skill in free-hand drawing, frequently apply themselves to the production of designs to be used in such arts as the manufacture of pottery, silk fabrics, paper hangings, etc., etc. These designs may constitute either modified forms of the objects themselves, such as new vases, goblets, plates, etc., or ornaments to be applied to the articles. Training in this department consists (1) in so moulding the ideas and imagination of the student that he may be able to originate the ideals which are to be embodied, and (2) in acquiring the power of transferring the ideals to paper. In general the power to transfer to paper is acquired before the ability to originate is attained, and indeed the latter is frequently absent where the former exists.

The power to originate designs of true merit can only be acquired by a careful study of the principles of art, and a thorough contemplation of the best pre-existing models. From these, new combinations may be evolved, and if the student pay judicious attention to the infinite variety of wonderful and beautiful forms which are constantly presented by natural objects, new elements, affording the most valuable and original designs,

may be obtained. It very rarely happens that designs of true excellence are evolved by the artist from the "depths of his inner consciousness." Almost all the best designs are combinations of existing forms, and hence the importance of extended and careful study.

Those who desire to acquire skill in the art of free-hand drawing, should devote their attention to it before commencing the study of mechanical drawing. In the latter dependence is placed wholly upon instruments; the eye and the judgment are never consulted in regard to the length of a line or the position of a point, and consequently, in those who depend wholly upon instruments, the power to lay down figures by the hand and eye alone becomes gradually weakened, or at least it ceases to acquire strength. If this weakening should take place before the faculties have been developed by practice and culture, it will be very difficult to restore them, therefore the student who desires to become an expert both in free-hand and instrumental drawing should always study free-hand drawing first. We have known many who became skilful mechanical draughtsmen after they had studied free-hand drawing, but we have never known a case of one who, after a prolonged dependence upon the aid of instruments, ever acquired that boldness of touch which constitutes the perfection of free-hand drawing.

4. *Instrumental Drawing.* In this branch the draughtsman depends entirely upon the aid of mathematical instruments for laying down lines and points with the necessary accuracy. The simpler branches of this kind of drawing demand no great natural ability; care, neatness, and such a knowledge of elementary principles as may be easily acquired by almost anyone, are quite sufficient, and the ability to apply these, forms one of the most valuable acquirements which a young man can possess. Mechanical drawing may be said to be the written language of the constructor, and it is far more clear, expressive, and unmistakable than any mere combination of words. Every man who at any time requires the services of the blacksmith, the machinist, the carpenter, the builder, or even the tinker, will find that the ability to give his ideas shape in the form of a working drawing will save him much time, trouble and expense, while to the young man who is learning a mechanical trade the art of drawing is as necessary as the art of writing.

PRELIMINARY STUDIES.

Drawing, like all other arts, requires for its successful practice a combination of science and art—of science that we may know what to do, and of art that we may have the necessary skill to apply our knowledge. The knowledge required by the student of drawing consists chiefly of a familiarity with straight and curved lines and their relations to each other, and with the phenomena of light and shade, for it is by the proper laying down of lines and putting in of shades and shadows that all the effects of drawing are produced.

Therefore, those who desire to become proficient in drawing of any kind should by all means first take up the study of elementary geometry, and make themselves thoroughly master of at least so much as is covered by the first four books of Euclid. The slight knowledge which is obtained by the study of what is known as *Practical Geometry*, is not enough; the student must not only know how to erect a perpendicular by means of a certain formula, but he must understand the geometrical laws by which the formula gives him the desired result. If he has not this knowledge, he will be continually floundering in the dark, liable to commit mistakes at every step, and making, at best, but slow and uncertain progress. On the other hand, those who have even an elemententery knowledge of geometry, are always sure of their ground; they know that certain lines must have such and such relations to each other as regards parallelism, length, etc., and they are not at a loss to know just what the results of a certain method of construction will be. They waste no time in applying superabundant and useless tests of accuracy, and they do not commit the fatal mistake of relying upon false tests.

We are the more emphatic upon this

point, because it is one upon which even professionals often fail. A striking example is to be found in a recent work on Mechanical Drawing, in which the author is very careful to caution us about having the blades of our T squares at perfect right angles with the stock! Now, to have them nearly at right angles, or square with the stock, is all right, but to spend any labor in securing great accuracy in this respect is, as we shall see further on, a great waste of labor. If the board is square the drawing will be all right, provided the stock and blade of the T square are firmly fixed together.

It is not intended, by what has just been said, to belittle the study of Practical Geometry, as it is called. To do so would be to insist that the student shall solve all the practical problems for himself, and this would be manifestly absurd. Every good text-book of drawing contains the more important problems required, and these should be carefully and frequently worked over until the student is familiar not only with the printed directions, but with the actual manipulations required, for in drawing, as in everything else, finger-skill (handicraft) is quite as important as theoretical knowledge. A sound knowledge of theoretical geometry is of great value to students of free-hand drawing, as well as to those who devote themselves to mechanical drawing, and to all it is invaluable as a means of mental discipline.

The instruments required by students of free-hand drawing are few and simple. A smooth board, some cheap but firm paper, and a few pencils of varying degrees of hardness are all that are absolutely necessary. The beginner must commence by copying simple lessons, never using compasses, straight edges, strings, or other devices for laying down points or measuring lines, for to do this will be to destroy confidence in one's self, to weaken the power of estimating distances and directions, and to induce general laziness and inattention. Above all things, avoid those ingenious devices which are constantly being described in our popular scientific periodicals, such as sketching frames, transparent slates, drawing windows, etc. By means of them you may be able to make a few worthless copies of engravings or drawings, but you will destroy your chances of being a draughtsman.

But while we would urge the student to avoid the use of instruments in *laying down* lines and points, it will be of great advantage to him to test the accuracy of his work from time to time by means of rulers, compasses or strings. In this way he will easily see which way his errors tend, and will get a hint towards correcting them. He will also be encouraged by seeing that practice and attention have enabled him to make perceptible improvement.

Nothing but practice and faithful attention will confer the necessary skill and power. Therefore make copy after copy of the lessons set before you; after a time pass on to sketching from actual objects, whether models or natural objects, and keep practicing at this. For directions as to the actual practice of the art we must refer our readers to the text-books, and those who cannot devote much time and effort to this department will find a series of very simple and useful lessons in some of the previous numbers of the Young Scientist.

For the study of mechanical drawing more elaborate instruments are required, though even at the best they are not very costly or difficult to procure. It is easy to find in the stores where artists' materials are sold, cases of instruments costing two or three hundred dollars, but these are more ornamental than useful. At the same time we must caution our readers against those cheap sets which are offered for sale by almost every stationer. They are made, like the peddler's razors, to sell, not to work with, and it would be utterly impossible to make a good drawing with them. A very fine set, containing, however, no instruments but those which are absolutely indispensable, may be had for five dollars, or even for three and a half.

The first step should be to acquire neatness in the use of the tools, and the most profitable way to attain this is to go carefully over all the problems of practical

geometry several times, laying the lines down with the utmost accuracy and delicacy that is possible. Give special attention to the more difficult and intricate problems; study the different tests for the accuracy of your work and apply them carefully. In addition to this, study the construction of your tools and the special points which enable you to do good work. Learn by practice to handle them with great delicacy. For example, practice until you can mark points on the paper with the legs of your compasses so delicately that the marks, though visible, do not injure the paper, and see how many circles, arcs, etc., you can strike from one centre before that centre disfigures the drawing.

After having acquired a knowledge of the properties of lines, and skill in laying them down, proceed to make copies of any good architectural or machine drawings that you can find. Having laid them all down carefully, in pencil, proceed to ink them in with China ink, and afterwards to color them with the proper colors. Try also to acquire the art of shading and flat tinting by means of lines drawn in ink with the ruling pen. This method of finishing a drawing is very neat, but to beginners it is exceedingly difficult. They cannot get the lines at the proper distances apart. Some lines are too far apart and some too close. The lines also are of unequal strength. This gives an irregular or *clouded* appearance to the drawing, and is very offensive to an experienced eye. Practice alone will enable the student to acquire the necessary skill and avoid these defects, though a good deal will depend upon certain manipulations of tools and ink, for which, unfortunately, directions are not usually given in the books. For the purpose of aiding the self-taught student we shall devote some attention to this in a subsequent article.

What we have said thus far, both as regards free-hand and instrumental drawing, refers, of course, almost wholly to the making of copies, either from other drawings or from the natural objects themselves. This, though a comparatively low step in the art, is an important one, and one that should be thoroughly studied. The higher departments, in which original design comes into play, requires far more thorough training and a wider range of knowledge. To make a drawing of a steam engine as it stands is one thing; to design an engine which shall have new and valuable features is another, and perhaps the latter should not be referred to the department of drawing, but to a separate and distinct branch. That which is very obvious in the case of the steam engine, however, is not so clear when we come to consider mere ornamental matters, and hence we find that most untrained persons who speak of drawing and advocate its introduction into our schools, do so because they believe that the pupils will at once be able to produce new designs which will be of great value in the arts. It is hardly necessary to say that in nine cases out of ten this hope will prove fallacious, and then will come a reaction and a great outcry about the uselessness of all such instruction.

Those who desire to acquire the ability to produce original designs which will have any value, either financially or otherwise, must devote themselves to the subject as to a life-work. The mind must be trained by long culture to appreciate that which is truly beautiful, and with most minds the extent of study required is very considerable. It is only the half-taught student that thinks he has acquired it all. In addition to this training, as regards perception of the beautiful, the student must lay up a large store of forms in their various combinations. The pencil must be kept in constant practice, seizing upon little bits of artistic work and fixing them so that they may be laid aside and afterwards worked into other combinations. Nature must be ransacked for new and beautiful forms, and the air, the earth, and the waters must be compelled to yield their tribute to the artist's portfolio. Even those regions which have hitherto been a sealed book to the multitude must be carefully studied, for Nature seems to have reserved for her lowest forms of life the finest work in this direction. The exquisitely beautiful forms of diatoms, desmids, polycystina, foraminifera, and other microscopic organisms afford a most extensive and hitherto totally unworked field for the designer.

Home-Made Telescopes and Microscopes—VII.

GENERAL REMARKS ON MAKING OBJECT-GLASSES.

THE directions for working glass surfaces to a correct figure, may appear to some too practical and characteristic of the workshop; but it is only by a strict attention and study of such details that perfection can be insured, and without their aid, the deductions of the mathematician must fail in their proof. Though the early training of a mechanical profession has familiarised me with such pursuits, yet I must confess that I am ignorant of the methods adopted by our best makers for working their minute object glasses; and, therefore, if some particulars may have the merit of originality, others are perhaps not in accordance with the most improved practice.

The first attempt to construct an object-glass (¼ in.) is recorded in the year 1850, on the then well-known form shown by Fig. 11. The back lenses had an excess of

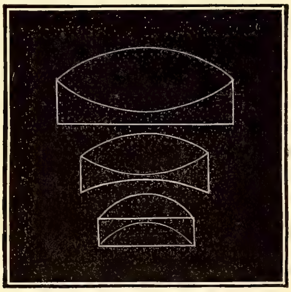

Fig. 11.

negative aberration, or were over-corrected, to enable the adjustment for covering-glass to be performed by the separation of the front lens, which was under-corrected for that purpose. But on attempting to improve the correction by a difference in the radius of the concave flint of the triple front, it was shown that a considerable alteration was here required to effect a material correction for color. Taking a ray at the focal distance from the front surface, and tracing its refraction through the triple, at all points, it appeared to enter the concave surface nearly as a radius from its centre. Consequently, under this condition, the effect of the dense flint was partly neutralised.

It then occurred to me to try a single lens for a front. With this combination no satisfactory result could be obtained with respect to achromatism.

Early in the year 1850, Mr. Lister was occupied with experiments for the purpose of improving the higher powers, and then introduced the *triple back*, which has since so eminently proved to be the grandest step towards their perfection, allowing perfect correction to be obtained with the most extreme apertures.

Having received early information of this improvement, I set to work and again tried the single front in combination with the triple back, and constructed a ⅛th on this system, which is considered excellent to this day. For several years I stood alone in my opinion of its advantages; but as numbers of our best object-glasses of the highest powers are now made with single fronts, I am in a better position for advocating this form, particularly as its success was found to depend upon a relative difference of focal lengths in the two back combinations not hitherto employed by others.

At first the single front with the back triple was not successful. Though color was nearly corrected there was a deficiency of aperture, and the combination was spherically under-corrected. On viewing another object under a thicker covering-glass, the definition was greatly improved. By placing other pieces of thin glass over the object, the front lens had to be drawn still closer to the others. This gave an increase of aperture and more perfect definition. A single front was then made, of the thickness which had been found to give the best result, ascertained from the measurements of the additional pieces of thin glass over the object, and the effect was all that could be desired. On finding that the correction for spherical aberration depended upon the thickness of the front lens, the path became easy.

Fig. 12 represents a ⅛th of 130° of aperture constructed on this system, six times the size of the original. The curves are not given as radii, but as the diameters of the

circles in thousandths of an inch—for I thus note them down for the convenience of making and finding the steel gauges and to prevent divisions into two-thousandths, which would frequently occur in

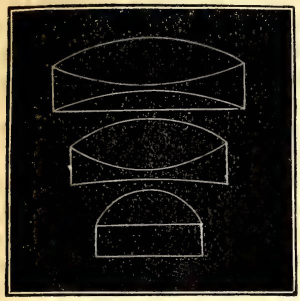

Fig. 12.

the corrections. The following are the curves:—back triple,—posterior of crown, ·312; three next surfaces, crown and concave flint, ·440; front flat, diameter of lens, ·173; density of flint, 3·630; ditto, of crown 2·437.

Curves or templates of middle:—Back, ·233; contact surfaces, ·233; front 1¼ inch, or ⅝ths inch radius; diameter of lens, ·138; density of flint, 3·686; ditto of crown, 2·437.

Single front of crown, ·100 or 1-10th template; diameter of lens ·093; thickness, ·057, measured from the top; density, 2·437.

The focus, or magnifying power, of the two back combinations is very nearly equal, and each 4¾ times that of the single front; for I have found that if the middle is of shorter focus than the back, that it is difficult to obtain satisfactory correction. The lenses are fitted into their cells without shoulders, as their diameter is only just sufficient to admit the full pencil of rays, and their surfaces are utilised to the extreme edge, a desideratum that can always be secured by a proper mode of working.

The aperture of this object-glass is 130°, which is amply sufficient for a good working ⅛th. In the triple back, the three cemented or contact surfaces are of the same radius, as I have not been able to ascertain that any material effect in the correction for spherical errors can be obtained by a difference in the two radii of the concave flint, and, therefore, for the sake of facilitating the workmanship, both faces are similar. I am aware, however, that some makers hold a different opinion and make the incident-surface of the con-concave much deeper, and the other longer in due proportion. The front of the triple is flat; but as the perfection of an object-glass depends in a remarkable degree upon the radius of this surface, a plano-convex lens cannot always be applied as a rule, for the curvature depends very much upon the nature of the glass employed in the construction, and the distance at which the lenses are placed asunder.

The correction for oblique pencils, and flatness of field, are mainly effected by an alteration in this radius, ascertained from the appearances of a globule of mercury, hereafter to be explained. Also, for the convenience of working, the posterior and contact surfaces of the middle lens are of smaller radii, and the required negative correction for color is obtained by an alteration in the concave incident-surface of the flint. The back and middle lenses are worked as thin as possible. It is an easy matter to make convex lenses to a sharp edge; but to insure the requisite thinness in the concaves, the edges are polished before the grinding is completed; and this is continued till they are seen to be as thin in the centre as may be deemed practicable, without the risk of breaking them through.

In the construction of the highest powers of the microscope, or such as are composed of three distinct sets of lenses, it must be borne in mind that the magnifying effect is obtained principally by the front lens; and the combined operation of the middle and posterior, is entirely corrective; and their application in any combination must always be so considered, and not as a means of obtaining additional power. If the front of an eighth or one-twelfth is tested alone, it will be found to magnify nearly as much as when the other lenses are replaced.

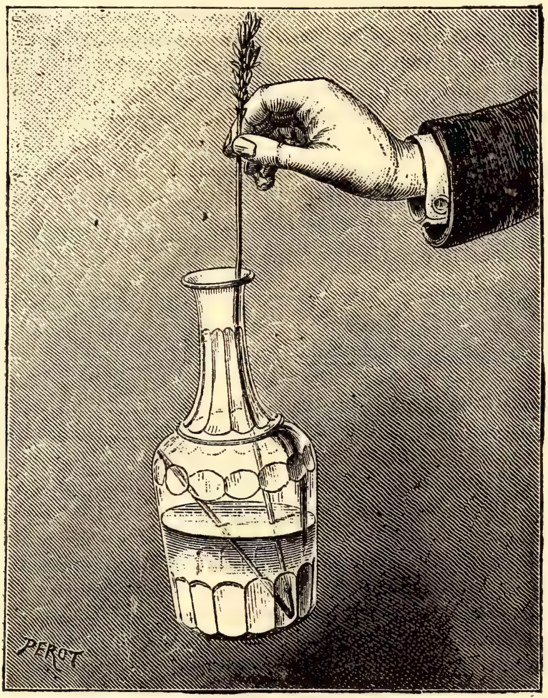
The single front has the advantages of facility of construction, and a command of any required extent of aperture; and

enables object-glasses of higher power to be made than would otherwise be practicable. For example, the radius of the front lens of a 1-50th is 1-120th of an inch, and the diameter is 1-70th. The difficulty, if not impossibility, of constructing a *triple* of such almost invisible atoms of glass may be imagined.

Science in Common-Place Things.

UNDER the somewhat taking title, "Physics Without Apparatus," our French cotemporary, *La Nature*, has published a series of articles which have been extensively copied and quoted. Unfortunately the title is a misleading one, for the author constantly uses *apparatus*, and in some cases he employs apparatus which can be obtained only from dealers in philosophical instruments. And it is still more unfortunate that the explanations and directions are in all cases meagre, and in many erroneous, some of his experiments not being in any sense illustrations of the principles which they are said to render clear. The engravings, however, are very fine as works of art, and we have therefore procured several of them, which we shall present to our readers with original and accurate explanations, and more minute details in regard to the best methods of performing the experiments.

Of the value and importance of experimental illustrations of the laws of science, no teacher of experience has any doubt. One of the great difficulties in the way of such experiments, however, is the expense of the necessary pieces of apparatus, and the difficulty of using them. Several writers have endeavored to suggest means for overcoming this obstacle—the most noteworthy attempt being that of the late Dr. Paris, in his "Philosophy in Sport made Science in Earnest." In a recent article upon this subject, the English journal, *Nature*, thus attempts to impress



LIFTING A DECANTER BY A STRAW.

upon its readers the wide range of experiments which may be performed with very simple means: "It is true that almost all the more important facts and laws of the physical sciences can be illustrated and explained by the help of experiments made without special or expensive apparatus, and requiring only the familiar objects of common life for their performance. The greatest exponents of popular science—and amongst them notably Faraday—delighted in impromptu devices of this kind. It is indeed surprising how, throughout the whole range of natural philosophy, the hand of the master can turn to account the very simplest and rudest of apparatus. A silver spoon, a pair of spectacle lenses, a tumbler of water, and a few sheets of paper suffice to illustrate half the laws of geometrical optics. A few pieces of sealing-wax, some flannel, silk, writing paper, pins, and glass tumblers will carry the clever experimenter a long way into the phenomena of electricity. These are things which any person can procure, and which any person can be taught to use. But their right use depends on the possession of accurate scientific knowledge, and a clear understanding of *what* the various experiments are to prove." To all which we say—Amen!

The first illustration which we take from *La Nature* is an old experiment tolerably familiar to the boys of half a century ago. The author of the article on "Physics Without Apparatus," gives it simply as an illustration of a *lever*, which it certainly is not. The old problem was: "Can you lift a bottle with a straw without tying the straw to the bottle?" The uninitiated were always obliged to give it up, but those who were familiar with the trick carefully selected a sound straw, free from bends or bruises, and then after bending it as shown in the figure, introduced it into the bottle or decanter. Then, on taking hold of the upper end of the straw, the bottle was easily raised. On examination we find that the straw is here pulled at one point and compressed at another. A straw subjected to a pulling strain will lift much more than the weight of a decanter, but if used as a lever it will bend and break with a tithe of that weight. The other part of the straw is in a state of compression. When we pull on the long or upper part it is prevented from coming out because the bend cannot slip up without shortening or compressing the other part of the straw. If the straw is strong enough to resist this the decanter will be held.

It certainly cannot be said that the straw is here used as a "lever." The principle by which we are enabled to lift the decanter is that a sound straw is able to resist a very considerable force when the latter is applied directly, either to extend or to compress it.

It will be found that it is much more important that the straw be perfect between the angle and the lower end, than between the angle and the upper end. Indeed, the slightest bruise or imperfection in this part will allow it to bend, and then it will be drawn out of the decanter. As an illustration of the nature and direction of strains, and the ability of materials to resist them, this experiment is very instructive.

The American Institute.

THE Fair of the American Institute promises to present unusual attractions this year. Amongst other new features, is the admission of the work of amateurs and apprentices free of charge. Amongst the judges in this department are some prominent ladies. So long as the Institute seeks by all legitimate means to foster education and the improvement of the young in industrial and artistic pursuits, just so long will it retain a firm hold upon the hearts of the people and secure that permanent success which can come only to earnest and worthy efforts.

One of Our Pond-Dwellers.

THOSE who take pleasure in examining the living creatures which find a home in our ponds and rivers, must often have come across the beautiful rotifer, of which we give an engraving. It is a conspicuous object, easily seen and examined under ordinary microscopes.

Figure 1 shows the *Noteus quadricornis*

as it is usually seen in the live-box or hollowed slip—swimming about flat. Very often, however, especially when swimming amongst the slender stems of algæ,

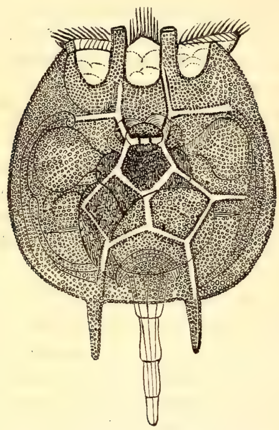


Fig. 1.—NOTEUS, FRONT VIEW.

etc., it turns up on edge and presents the appearance shown in Fig. 2. In this position the young and inexperienced microscopist would hardly recognize it as the same animal. This is, however, a frequent circumstance in regard to microscopic objects. Very many diatoms and

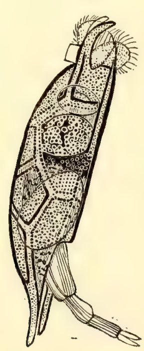

Fig. 2.—NOTEUS, SIDE VIEW.

desmids present such an entirely different appearance when seen in front view and in side view, that unless the microscopist has had considerable experience, or has actually seen the objects rolling over so as to present both views, he will be unable to recognize them.

The Noteus is sufficiently transparent to disclose the working of its internal organs under the microscope. If a little carmine be added to the water the working of the cilia is beautifully seen. The best way to use the carmine is to grind a little of the best water color upon a slab or a very smooth plate, and add a small quantity to the water by means of a camel-hair pencil. The carmine ordinarily sold in powder is too coarse.

Astronomy for Amateurs.

BY BERLIN H. WRIGHT.

(Calculated for the Latitude of New York City.)

THE PLANETS—SEPTEMBER, 1880.

	D.	H.	M.

"	I,	16	10	15	"	Tr.	Eg.
"	III,	21	8	33	"	Tr.	Eg.
"	I,	24	9	9	"	Oc.	Re.

EXPLANATION:—Oc., occultation, or passing *behind* the planet; Tr., transit, or passing *before* or across the face of the planet; Ec., eclipse, or passing into the planet's shadow. During this month the disappearances spoken of will all occur at the left or east of the planet as the shadow is thrown eastward. Dis., disappearance or beginning; Eg., egress or ending. It will be interesting to watch the disappearance and following reappearance of Sats. I and III. The former, passing across the face of Jupiter, may be seen in transit as a black round spot, while the latter disappears entirely behind the planet, to reappear two hours later at the left.

THE MOON, V.

A little west of the western termination of the Canal of Hyginus begins the Canal of Ariadæus; it is larger, broader and probably deeper than the former, having been traced westward over 175 miles, or to the shore of the Sea of Tranquility. Both of these canals may be best seen about the First Quarter. Manilus (95) is a cavity 25 miles in diameter and 7,700 feet deep; its ring is broad, and capped with craters and high peaks. 99 and 101 are brilliant crater rings, and 96 and 98 are very dark hollows. Rhæticus (104) is an irregular crater exactly on the Moon's equator. These complete all of the most conspicuous and interesting objects in the First or Northwest Quadrant.

SECOND OR N. E. QUADRANT.

Near the crater Schrœter (106) have been seen what were supposed by some to be a work of art. The spot is indicated on the map by the fine lines below 106. The discoverer described them as a collection of dark gigantic walls, visible only when close to the terminator (the boundary between the light and dark portions) and extending 23 miles in each direction, being arranged on each side of a principal wall from which they slope off S. E. and S. W. respectively at an angle of 45°. N. is a bay where no craters are to be seen, with ordinary instruments, while upon its N. E. shore lie three grand craters, Eratosthenes (110), Stadius (111), and Copernicus (112). The first two are connected by a steep mountain range 4,500 feet high. The former is 37 miles in diameter, and has a central hill, while the latter is 42 miles in diameter and is level. The ring of the first rises 16,000 feet above the inner surface, and the latter only 130 feet, scarcely visible. East of 111 lies one of the grandest of lunar craters, Copernicus (112), 56 miles in diameter. It has a central mountain that boasts of six heads, two of which are very conspicuous, a noble ring, made of terraces and distinct heights, separated by ravines. The nearly circular summit of the ring rises 11,000 feet from the bottom (the height of Ætna). This crater forms a brilliant spectacle at the time of Full Moon, likened by some to a string of 50 pearls. It is surrounded by radiating walls—lava streams. It is beautifully figured in "Outlines of Astronomy," by Sir John F. W. Herschel, Pl. V, Fig. 2. So said to be by Rev. T. W. Webb, in his "Celestial Objects," though the figure given in "Chamber's Astronomy," (after Nasmyth), Pl. III, Fig. 29, bears no resemblance to it whatever. The figure in Herschel answers more nearly its appearance when viewed with an aperture of 3 or 4 inches, and a day or two after First Quarter.

Penn Yan, N. Y.

Drilling Glass.

One of our exchanges gives the following directions for making holes in glass:—

Stick a piece of stiff clay or putty on the part where you wish to make the hole. Make a hole in the putty the size you want the hole in the glass, reaching to the glass, of course. Into this hole pour a little molten lead, when, unless it is very thick glass, the piece will immediately drop out.

We would advise our readers not to try this on any article that they value. In nine cases out of ten instead of making a clean hole, the molten lead will break the glass all to pieces. A clean round hole may sometimes be made in a plate of glass by shooting a bullet through it. In most cases however the bullet shatters the glass.

To Take Bruises out of Furniture.

Wet the part with warm water; double a piece of brown paper five or six times, soak it in warm water, and lay it on the place; apply on that a warm, but not hot, flat-iron, till the moisture is evaporated. If the bruise be not gone, repeat the process. After two or three applications, the dent or bruise will be raised to the surface. If the bruise be small, merely soak it with warm water, and hold a red-hot iron near the surface, keeping the surface continually wet—the bruise will soon disappear.

The Egyptian Cubit.

In noticing the labors of the International Bureau of Weights and Measures, Abbe Moigno regrets the choice, as the unit of measure, of the ten-millionth of a meridional quadrant, "a unit fatally indeterminate," since the meridians vary in length. He suggests, as a better standard, the cubit of the Great Pyramid, which represents the ten-millionth of the earth's polar axis. Sir John Herschel made the same proposal, nearly thirty years ago, and it is somewhat remarkable that his views should be now advocated by *Les Mondes*, the leading French scientific journal.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

Wanted, "Butler's Family Aquarium;" will give in exchange two books, entitled "Laughing Gas" and "De Walden's Ball-room Companion." E. R. Brown, Box 25, Covington, Ind.

Wanted, a good microscope in exchange for a scroll saw; instrument must be in good order, and magnifying power of from 200 to 300, or 400 diameters. H. E. Rhodes, Brighton, Iowa.

A patent spectograph, cost when new $1.25; rare minerals, birds' eggs, and postage stamps, to exchange for minerals, foreign coins, Indian relics, or offers. Frank F. Fletcher, St. Johnsbury, Vermont.

Eggs, of the English sparrow, for good specimens of other birds' eggs; botanical specimens mounted and unmounted to exchange; lists exchanged. C. R. Hexamer, New Castle, Westchester Co., N. Y.

What is offered for one of the Climax extension step ladders? H. E. Phelps, Manhall, Michigan.

To exchange, a $3 microscope for some old issues of Canada postage stamps. Wallace Ross, Lock Box 97, Rutland, Vt.

Wanted to exchange, Colorado minerals, such as jasper, smoky quartz, silicified wood, etc., for good specimen fossils, or perfect crystals of minerals of other localities. H. F. Wegener. Denver, Colorado.

One Natural Philosophy, one Bryant & Stratton's Counting-house Book, and two long bows, with arrows, to exchange for cabinet specimens or curiosities. W. D. Wright, Lock Box 17, Bremen, Indiana.

Wanted, coins, minerals, and type; send lists of what you have and what is wanted in exchange. A. Campbell, Derrick City, McKean Co., Pa.

An Excelsior Printing Press, with equipments, comparatively new, cost over $47, for double barrel breech-loading shot gun, with reloading tools and shells. William A. Hervey, Box 134, Taunton, Mass.

To exchange, 400 stamps, all different, in a stamp album, for a small printing press with type, etc. Arthur D. McGerald, 106 Bird Ave., Buffalo, New York.

To exchange, $5 pair of telephones for mounted microscopic specimens, good objective, lathe chuck, watch, type and cases, or offers; describe offers. Wm. R. Brooks, Phelps, N. Y.

What offers for Roger Scroll Saw, 55 large patterns. J. Brower, 3,150 Frankford Road, Philadelphia, Pa.

Scroll sawing outfit, $6; microscope, $3; pocket telescope, $1; Gaskel's Compendium, $1; Williams' Complete Painters' Guide, $2. What offers for all or part; printing outfit preferred. F. W. McNair, Box 46, Fennimore, Wis.

$7 worth of books or papers, to exchange for a Household microscope or offers. Jonas D. Rice, 221 Academy St., Mercer Co., N. J.

Idaho cabinet minerals, books, revolver, stencil outfit, an electrizer, for well-bound books of travel, biography, history, science, masonry and others of an instructive nature. J. P. Clough, Junction P. O., Lemhi Co., Idaho,

Dumb bells of all sizes, to exchange for most any thing; send for circular containing weights of them to J. P. Donohue, Box 7, Davenport, Iowa.

Wanted, scientific books and papers, microscope, drawing instruments, telephone, stamps and coins, in exchange for scroll saw, type, cards, revolver, shot gun, magazines, scientific books, or almost anything. W. L. Goodsell, Bath, N. Y.

A pair of New York Club skates, worth $3.50, also coins, minerals and postage stamps, for books or offers; correspondence invited. E. F. Greene, P. O. Box 889, Bath, Steuben Co., N. Y.

A nice marine oil painting, ready framed, worth $5.00; state what is offered in exchange. C. Hammond, Artist, P. O. Box 47, Chatham, Barnstable Co., Mass.

Photographic camera, one portrait and one landscape tube, with chemicals complete, in exchange for medical books. J. Frederick Herbert, 1,324 Poplar St., Philadelphia, Penn.

Trump's and Russel's scroll patterns, worth $10; for large lenses preferred. H. J. Peters, Rogersville, Ohio.

SCIENCE IS KNOWLEDGE. — INDUSTRIAL PUBLICATI — KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, SEPTEMBER, 1880. NO. 9.

A Breakfast for a Whale—What it Was, and How it was Got.

BY A. W. ROBERTS.

MANY people who try to keep an aquarium fail in their efforts, because they think that fish can find in the water all the food that they require. The extraordinary quantities which some marine animals require was very fully impressed upon my mind upon one occasion, when I had to provide a breakfast for a whale; and although, strictly speaking, a whale is not a fish, yet the lesson is the same, and I will therefore relate my experience.

One hot sultry afternoon, when trying to copy one of Birket Foster's beautiful landscapes (for when not collecting I was trying to learn to draw), I had become tired of myself. I had tried and tried to acquire the beauty and "touch" of his penciling, but had utterly failed. So, out of sorts, and out of humor with myself and things in general, I started for my favorite pond and woods (I had got to calling the woods and streams my big medicine, for in them I lost all my troubles). In this particular pond grew many varieties of plants; the water teemed with animal life; many birds had built their nests in the shrubbery that grew on its margin, and a full orchestra of tree toads and various kinds of frogs were in attendance as nature's musicians.

When I reached this pond I proceeded to spread out the many newspapers that I had brought with me to wrap the plants in. In one of them my attention was attracted by an announcement in large type of a wonderful young man from the East, who had been secured to take charge of the aquaria at Barnum's Museum (the old museum), whose knowledge of fish was something astonishing, so much so that he knew their language, etc., etc., etc. When I began reading this article I was standing up; when I got half way through

I sat down; and when I got to the end I was rolling on the grass with laughter. Getting myself together, I determined to know all about that young man before I slept. If he knew more than I did he was just the person I was in search of. So, determining to cultivate him, I made a collection, consisting of every variety of fresh-water plant within five miles of the pond—being very careful not to take a plant of which I did not know the class, order, species, and common name. In three hours I had a beautiful collection, carefully assorted, bunched, and washed.

Remaining in the woods till nightfall—for I had become a deplorable looking object, spattered over with mud, broken boots, torn clothing, and scratched face and hands—I preferred darkness to daylight when going through Brooklyn. Reaching the Museum, I paid my way in. Leaving the bundle of plants with the doorkeeper, I started in search of the Eastern fish linguist.

There he was, pacing up and down, his hall deserted on account of the "great moral drama" going on in the "Lecture Room." Getting right in behind him, I ventured to remark, "Mister, there's a big rock on top of one of your eels," (it was only a conger eel that was having a good time under a stone), but he neither paused nor made me any reply, but paced right ahead. He evidently "knew eels," and I thought to myself I must bait again; this time I'll try him with some Latin, for I hadn't forgotten my first lesson in scientific botany, taught me at the John Street seed store. Right ahead of him was a tank containing a large mass of stonewort. Closing in on him again, I exclaimed, "My gracious, what a beautiful specimen of *Callitriche pedunculata.*" He turned short on me and asked what did I say? I replied, in a careless off-hand way, "Oh, I was merely admiring the robust growth of the *Callitriche pedunculata.*" "Oh, y-e-s," he replied, at the same time cautiously and critically examining me from head to foot, then up again. I knew I had hooked him this time. I could see he was bothered, and was trying to place me, but my broken boots, muddy and torn clothing, totally disguised me.

"Are you interested in aquaria?" he asked.

"A little," I replied.

"Are you acquainted with fresh-water fishes?"

"A few," I replied.

Then, leading me to a tank, he asked me if I knew the name of a small fish that was swimming about in the water.

I replied that its name was *Pomotis chetadon*, and that it was one of the handsomest varieties of all the sun fish.

Every minute he grew more pleasant, and I began to come out of my muddy disguise a little, for I had come to the conclusion that I could match him on fresh-water aquaria; still I was anxious to learn. He now became very courteous and affable; for this I felt thankful, as I had often desired to stock some of the large tanks free of charge, that I might study more closely the habits of fish and plants; and I felt that now was my opportunity.

Presently, he asked if I could obtain some plants for him, if he gave me a list of those he wanted, and what would I charge?

In going over the list, I crossed out all that were not in the bundle down stairs, which left me some seven varieties that were not down on his list, and I suspected he had never heard of them or seen them. Then, asking to be excused for a few minutes, I passed down stairs, returning again with the bundle, (Oh, it was a big one). Hardly taking time to cut the yards of string with which it was tied, I began displaying the plants on the floor, at the same time calling off their class, order, genus, species and common name. Fifteen varieties in all, not to mention many kinds of aquatic insects, larvæ, and small molluscs, that went scrambling over the floor.

Well, if you could have seen that young man from the East; for a minute or two he hadn't a word to say. My last move had been executed so quickly and unexpectedly, that I had taken him completely unawares.

His admiration was so honest and outspoken, that I felt already repaid for my

trouble, and that we should become the best of friends in the future.

He pressed me hard to take money, but I refused it, telling him that I felt already paid in anticipating the enjoyment I should derive from seeing the plants in the tanks. Then came the offer of complimentary tickets; these I also declined, as they were of no use to me, (my opinion of Barnum's was not of the highest.) Wasn't there anything he could do for me? I replied that at present not a thing, but, perhaps, in the future, I'd give him a chance to pay me off. He asked me for my address, and when I gave it to him, the same odd puzzled look came over his face, as he again took a look at my wardrobe, and I said to myself, "He's wondering if I live on the fifth floor of a tenement, or in a brown stone front." When I reached home, and went over my adventure to my mother, we had a hearty laugh over it.

Next day, when, arraying myself in broadcloth, new hat and "party" boots, vest and kids, a telegram came, requesting me to come to the Museum immediately. This message puzzled me greatly, but at last I concluded that "Ali," the keeper of the hippopotamus, had stolen all my plants and fed them to "Hippo," and that either by money or coaxing, a new lot was to be obtained. Over I hurried, and when I reached the Museum, great was the astonishment my Eastern friend showed over my changed appearence, but greater was mine when he suddenly asked, with the greatest concern: "Did I know anything about whales?"

"Wait one moment," I replied, "till I sit down and get my breath, for I've run nearly all the way;" and I said to myself, "I must contemplate this thing."

Presently, he repeated the question, "Did I know anything about whales?" and showing more anxiety than before.

"Oh yes," I replied, just as though I was a second Jonah.

"That's all right," said he, "come with me; there ain't a moment to be lost, and I'll show you the 'old man.'" Said I to myself, "Be on your guard; the Wild Man from Borneo has lost his only son, and they are going to snake you into the old man's cage to be adopted." I didn't follow my new friend too closely, and felt that I'd feel much better if I was once more on Broadway. Presently, we arrived at a door that fitted into a tall box-like compartment, which reached to the ceiling, with one small window near the top. Taking out a key he whisked in, the door closing after him with a snap. The stairs from the entrance led up near this room, and I was about to take them, when my friend suddenly opened the door and smiling all over said, "Come in, come in, and I'll introduce you." In I went, and there sat a rather oldish looking man, with a bald head, busy writing. As soon as he paused, my friend remarked: "Mr. Barnum, this is the person I've been speaking about." I was so mixed up that I forgot to say, "How are you, sir," but stood half upright without saying a word. "Well," he remarked, "so you are posted on whales?" I scarcely knew what reply I made, but suppose I said, "Yes, sir." Then he informed me that I must have at least 200 pounds of live fish in the whale tank by ten o'clock next morning. I was going to reply that I couldn't do it, when my Eastern friend winked and nodded to me to say yes, so I replied, "All right, sir." I began to take in the situation. It was evident that I was engaged to obtain a breakfast for a whale that was on the way. I was sorely perplexed, but didn't show it, and was too proud to ask any questions. I had never collected any salt water fish, didn't know where to obtain them, or what kind were fitting for a hungry whale, the size of the whale, nor how large the fish ought to be.

Before starting I was furnished with $50 to pay expenses, and a large amount of passes. How I went to work, and what my success was, I will tell in my next.

— An eccentric individual thinks the government should at once put a stop to boring and pumping for oil. He fears that the oil is drawn from the bearing of the earth's axis, and that the earth will cease to revolve when the lubrication ceases.

Three Amateur Workers—and What They Did.

BY FRED. T. HODGSON.

PERHAPS you know Mr. Carpenter? Well, if you do not, let me introduce him to you. Here he is. You see at a glance, that he is a kind man: fond of his three children—Fred, Jessie and Ellwood—who are in return, very much attached to him. He is a good father; they are good children, and all are equally fond of Mamma Carpenter, who thoroughly believes there are no children in the world so good and so clever as hers; or a man so kind and wise as Papa Carpenter. No doubt, you have met Mr. Carpenter before, in some place that you cannot now call to mind; or, maybe you are acquainted with the boys—Fred and Ellwood—and it may be that you have seen Jessie, or that your sister knows her well. At any rate I wish you all to get acquainted with each other, for if all goes well, you will be in each other's company quite frequently during the coming months, and with your permission I will make the necessary formal introductions:

Mr. Carpenter, permit me to introduce the Reader. Reader, permit me to introduce Master Fred Carpenter. Miss Jessie Carpenter, allow me to introduce the Reader. Reader, Master Ellwood Carpenter. Mrs. Carpenter, who is now busy superintending the preparations for tea, will, at a later period, permit you to be introduced to her, and I am sure you will never regret it. You no doubt see that Fred is about thirteen years old, which he will be on his next birthday; and Jessie, the sunbeam of the house, will be eleven on the fourth of January next; and Ellwood, the harum-scarum boy, the plague of his sister, the pride of his father, and the joy of his mother, has just turned nine, and is as mischievous as boys generally are at about that age; but Jessie thinks he is "just awful," which I suppose must mean something very dreadful, if one may judge by the way she expresses it. Fred used to be mischievous, but this last year or so, since he "passed" for the higher school, he has been more staid, and has applied himself closer to his studies, much more so than he used to do; and Jessie, who, by the way, is a good judge, says he is the best boy in the country, and Ma and Pa, yes, and Ellwood, too, believe her.

Fred likes to work with tools; to be "making things," fixing up the fence, repairing the gates, and mending anything about the house that may be broken. Nothing pleases him better, after he arrives home from school, than for his Ma to ask him to repair some piece of kitchen furniture, or for Jessie to entreat him to put an arm, leg, or head on her doll, or to fix her doll's cradle, chair, or carriage. Last Fourth of July, Ellwood wanted him to make a wagon; a boy's wagon, you know; one with solid wheels, with holes through their centres for axletrees of hard wood to go through. Fred went to work and made one, but such a wagon! You never saw its like before. Of course it had wheels, but such wheels! They were made out of one inch rough boards, and were about eight inches in diameter; they tried to be round, but couldn't. When put on the axletrees and moved around, they wobbled and staggered worse than a paper boat would in a mill-race. An empty cracker box did service on the two axles for a box, and for a time Ellwood was delighted with it. The first person allowed to ride in it was Jessie, and she was nearly as proud of the vehicle as Ellwood himself; for every one she met that day she had to tell them that Fred had just made Ellwood a "real nice wagon," and that she had had the first ride in it.

All the tools Fred had to make the wagon with were an old rusty saw that he found in his father's stable, his father's big jack-knife, a gimlet, a hammer, and a piece of three-quarter inch round iron about two feet long. He used the saw to cut out the wheels and axles, of which the former was quite a job to do; he managed it, however, by cutting the wheels into many-sided polygons, and then whittling the corners off afterwards with the jack-knife. The gimlet was used for boring holes through the bottom of the cracker box, so as to fasten it on the two axles which it held together; it was also used for boring five or six holes through each of the wheels in their centres, after which

the round bar of iron mentioned above was made red hot in the kitchen fire, and while in that state driven through the centre of each wheel, thus making a hole large enough for the hard-wood axles, which, by the way, were whittled out with the jack-knife and saw. These tools were so rude, and so utterly unfit to do anything with in making the wagon, that Mr. Carpenter, who had been watching Fred work, promised to buy his boys some tools in the Fall, and have a little workshop fixed up for them in the barn, which is not far from the house. He also said he would explain what each tool was for, and show them how they were to be used. Of course the boys were pleased—what boys wouldn't be?—for they knew that whatever their father promised them he would surely do; and on this very evening, a few moments before you were introduced into the family, Mr. Carpenter had said to Fred that he thought he would go to the hardware store on the next day and purchase a few of the tools he had promised him and Ellwood, as the evenings were beginning to lengthen out. "To-morrow," he said, "I will have a place prepared in the barn, and will procure some lumber and the tools I spoke of, and if I am not otherwise engaged, I will instruct and assist you in making a small work-bench, and after that is finished I will show you how to make boy's wagons, hand-sleighs, flower stands, stools, and many other things that will be amusing, instructive, or useful." "Oh yes, Papa!" said Jessie, "and won't you show Fred how to make girl's workboxes, doll's cradles, and things?" "Certainly, my dear," said Mr. Carpenter, "I'll show him how to make a whole set of furniture for your doll, and how to build a nice little play-house to put the furniture and doll into; but you must not be impatient, my dear, for you know Fred will not neglect his studies for the purpose of 'making things,' as you express it, and he must also have time to play with the boy's outside, for I cannot allow him to be kept at work all the time, either at his studies or in the workshop I am going to prepare for him." "Oh, I'll wait, Papa, until he gets all the other things made, and then, if Mamma doesn't want him to make or mend something for her, I'll ask him to work at some of the nice things you say you will show him how to make for me."

"I want another wagon," said Ellwood, "for the one with the cracker box on top, that Fred made me last Fourth, is all broken. One of the wheels is split in two, and the axle on the back end is broken, and I can't pull Jessie around with it on three wheels, so I want Fred to make me a wagon first. Can't he, Pa?" "Well, Ellwood, you know," said Mr. Carpenter, "you must wait. Fred will have to learn a good many things before he will be able to make even a fair-looking wagon or cart. And besides, you must not tax Fred too much, he may want to make something for himself before he begins work on your wagon, and in that case you will have to wait." "But I can make a wagon myself, Pa, if you will only let me have the tools," said Ellwood. "I doubt it very much, my son; I'm afraid it would not be so good a one as Fred made you last summer, and which you now seem to despise. However, Fred will, no doubt, make you one as soon as possible, after he has learned to use the tools I shall buy to-morrow."

All this conversation had taken place but a short time before the "Reader" had been introduced; in fact, the introduction, which was somewhat abrupt, interrupted it, and as tea was announced shortly afterwards, it was not resumed again that evening. In the morning, however, at breakfast table, after Fred, Jessie, and Ellwood had gone up-stairs to prepare for school, Mr. Carpenter told Mrs. Carpenter of the promises he had made to the children. She was quite pleased to hear that he was going to purchase tools, lumber, and other necessary materials, but she expressed a fear that some one of her darlings might get cut or injured if they were allowed to handle edge tools, when their father was not present to guide their actions. Mr. Carpenter soon set her fears at rest on this point, by saying that he would see that Ellwood did not get any very dangerous tools to use, and that so far as Fred was concerned, she need have no fears, for he is such a careful boy, and will handle

the tools in such a manner that no serious accident will happen. Mrs. Carpenter also suggested that, as the boys were going to be taught by their father to make useful things, it would not be out of place if she undertook to give Jessie a few lessons now and again, in making such things as will be necessary to dress her doll in good shape, and decorate and properly finish the interior of her play-house, which Fred will no doubt build for her. Mr. Carpenter thought the idea a good one, and it was decided at once that the boys should have a workshop and tools, and should be taught how to use the latter, and that Jessie should learn housekeeping on a small scale—in a play-house—and many other things that a good little girl ought to know.

Reader, you and I will watch these three young people while at work. We may be able to learn something from them or their instructors.

Let us see!

(To be continued.)

Home-made Telescopes and Microscopes.—IX.

GENERAL REMARKS ON MAKING OBJECT-GLASSES.

In May, 1856, I made the first 1-25th with a single front lens of 1-30th in diameter; I am doubtful whether a triple front could be made even of this size, with any positive certainty of accurate workmanship.

From the $\frac{1}{8}$ and upwards, perfect correction may be secured with a single front. It is, however, barely possible to make a good 1-5th with this form, and in a $\frac{1}{4}$-inch it fails altogether; there is a kind of secondary spectrum that cannot be got rid of. It is not easy to define all the reasons why it should succeed perfectly with the highest powers, and the correction be imperfect with the lower ones named. With smaller apertures the errors of spherical aberration cannot be so well corrected by giving thickness to the front lens; and as there is considerable distance between this and the middle, the colored rays from the uncorrected front are so far separated that any corrective action of the back systems is incapable of recombining them. When an object-glass is spherically under-corrected, the focus of the central rays is longer than that of the marginal ones, as in a simple lens. If all the rays are brought to one point, the interposition of a plate of parallel glass projects the outside rays to a greater distance than the central ones, and produces a similar effect to a concave lens, or that of over-correction; and it is for this reason that a certain thickness of glass before, or in the substance of the front lens has such a remarkable corrective power, which is most appreciable with a very large aperture. Where this is comparatively small, as in a $\frac{1}{4}$-inch, the influence of a thick front does not appear to be sufficient to enable the final correction to be obtained by this means alone. The anterior lens must, therefore, either be partly achromatised, or made of a glass of higher refractive and less dispersive power than any at present known.

It is well known that, in a doublet consisting of two single plano-convex lenses, both the spherical and chromatic aberrations are considerably less than in a single

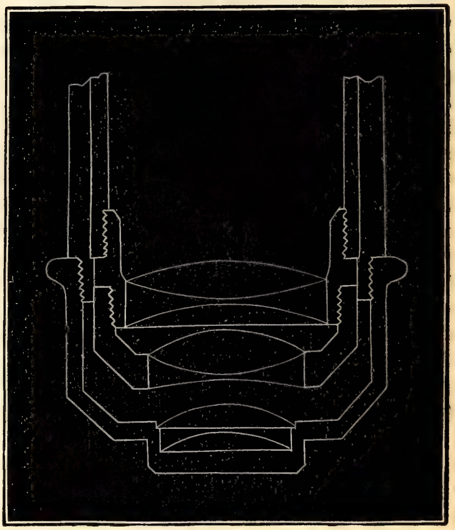

Fig. 13.

lens of the same magnifying power. I have for this reason proposed to construct the higher powers with two single lenses

in front, of equal radius, as shown by the cut. The correcting thickness should be thrown in the front lens. If they are set in contact, the magnifying powers will be nearly as their sum; they may therefore be made of double the radius, and consequently nearly twice the diameter, which, of course, would lessen the practical difficulty of working a 1-50th, and enable us to go even beyond this power. A partial experiment with a ¼th, having this "doublet" front, has proved that perfect correction for color is the result. But in the form tried, the spherical aberration was so considerable, as to require an entire reconstruction, for which I have had no leisure; and though the entire success of the idea is yet unproved, I venture to record it, in case I may never be able to take up this subject again, as I am of opinion that a very perfect object-glass may be made of this form.

IMMERSION OBJECT-GLASSES.

These combinations are under-corrected, and not suitable for use in any other way. The plan is an old one, and objectives were constructed on this principle by Amici and Ross many years ago. That such lenses give brighter and clearer definition, with the highest powers, from the 1-12th upwards, is unquestionable.

BRASS CELLS FOR OBJECT-GLASSES.

For the brass setting of object-glasses, it is necessary that the worker should possess a good foot-lathe; if provided with a self-acting arrangement for chasing up the short screwed parts of the cells, this will insure greater accuracy of workmanship. The setting or metal work of an object-glass must always be made before the lenses are commenced; three steel gauges are to be first formed, of a width exactly corresponding to the diameter of the intended lenses; this gauge I make out of a piece of sheet steel, with three arms of the three diameters required. A chuck should be fitted to the lathe, and cut out to the standard thread now generally adopted for object-glasses; into this the brass setting is fitted, and each cell screwed on, and turned out in succession to the proper size. I leave no shoulders at the back of the cells, but bore them clear through.

Triblet tubing is not sufficiently accurate for the outer shell of the highest powers; it is better, therefore, to make this of one casting, and bore it out of the solid, from its own chuck, and finish to the size with a fluted rimer. I have always made the inner tube, containing the back lenses, to traverse to and fro, in preference to the front lens, as the object is not thereby lost sight of during the adjustment, which is performed in one-third of a revolution of the outer ring, which has an inclined groove cut in it, acting on a screwed pin connected with the inner tube. This plan is more simple in construction, and less liable to derangement than the one commonly employed.

Our American Geysers.

THE two most wonderful geysers in the world, those known as "The Giantess" and "Great Geyser," are located in our National Park, on the Yellowstone River. Here, within an area of sixty miles square, in the north-west corner of Wyoming Territory, are collected such a variety of natural wonders, that, when the ways of approach are open, Americans will not need to leave their own country in order to view the grandest of all natural phenomena. Through one portion of this park flows the Fire Hole River; and it is in that part of its valley known as the Fire Hole Basin, that these Geysers are found. Here within an area of about five square miles may be found from twelve to fifteen hundred springs, with basins of all sizes, from a few inches in diameter to three hundred feet. These springs are of three kinds: 1. Those in which the ebullition occurs only at intervals, which are the true geysers; 2. Those which are constantly boiling; and, 3. Those which are in a state of repose.

The general appearance of these geysers is well shown in the illustrations on next page, though their grandeur and magnificence can never be even faintly appreciated unless they are seen in action. An eye-witness thus describes them:

"On a search for new wonders, leading

THE GREAT GEYSER.

THE GIANTESS.

AMERICAN GEYSERS.

us across the Fire Hole River, we ascended a gentle incrusted slope, and came suddenly upon a large oval aperture with scalloped edges, the diameters of which were 18 and 25 feet, the sides corrugated and covered with a grayish-white silicious deposit, which was distinctly visible at the depth of 100 feet below the surface. No water could be discovered, but we could distinctly hear it gurgling and boiling at a great distance below. Suddenly it began to rise, boiling and spluttering, and sending out huge masses of steam, causing a general stampede of our company, driving us some distance from our point of observation. When within about forty feet of the surface it became stationary, and we returned to look upon it. It was foaming and surging at a terrible rate, occasionally emitting small jets of hot water nearly to the mouth of the orifice. All at once it seemed seized with a fearful spasm, and rose with incredible rapidity, hardly affording us time to flee to a safe distance, when it burst from the orifice with terrific momentum, rising in a column the full size of this immense aperture to the height of 60 feet; and through and out of the apex of this vast aqueous mass, five or six lesser jets or round columns of water, varying in size from six to fifteen inches in diameter, were projected to the marvellous height of 250 feet."

The Great Geyser, as shown in the illustration on the preceding page, differs from the Giantess, in that its action is more violent. With scarcely any preliminary warning, a volume of hot water, eight feet in diameter, is thrown up to the astonishing height of 200 feet. So steady and uniform does the force act, that the column of water appears to be held in place for some minutes. This violent action takes place at regular intervals of about thirty-two hours.

Ornamental Turning.

TO the novice in ornamental turning, the more simple the apparatus to commence with the better, and it will be advisable not to have too much in the shape of instruments to begin with; if this is the case, they all come in for a small share of patronage, and little or nothing is done with any. In order to give the tyro some idea of the best means of fitting up a workshop, and using its contents, we propose detailing here the necessary items to commence with. First, then, we must have as a groundwork, a good lathe, and the one we recommend will be a 5-inch centre, with a traversing mandrel. This is not absolutely necessary, because, by practice, it is not a very difficult process to cut a screw without its aid, but as there are times when its use will save a deal of trouble, we certainly advise it. As an instance of its use, take the lid of a snuff-box, which is so short as a rule that it becomes a very difficult matter to insure a true thread, and as blackwood and ivory are so expensive, it is policy to save it at all risks. This, however, must remain with the person who is about to invest his money in one of these interesting instruments, and from what we have lately seen of their productions, it cannot be wondered at that so many are devoting their attention to it. Having obtained a lathe as described, if quite a novice, it is a great advantage to become efficient in plain turning before aspiring to the ornamental branches. When sufficiently expert in the use of the gouge and chisel, attention may be turned to the higher branches, and we have found that the best way to proceed is to first procure a good slide-rest fitted with a metal cradle and stops, to place the T of the slide to turn a true surface or cylinder. This is very essential, as it saves the trouble of adjusting the slide at each movement. An over-head-motion is now made with two cast-iron standards with triangular bar at the top, and a round bar with pullies on a drum. On it, revolving between two steel centre screws on the top bar, is fitted a carriage in metal, through which passes an iron bar with a cast-iron ball on the end, adjustable as to distance. This is to form a counterbalance to alter the tension of the band upon the various instruments. On the front end are two guide pullies to conduct the band to its position. The lathe now begins to assume the form of an ornamental turning one; a few more additions, and we make a start—an eccentric

cutter, a drilling instrument, a vertical cutter, and a few tools for each. We may now in reality begin to work, and with such an assortment of tools as named, much beautiful work may be done. As to what it will do, it is a difficult matter to explain by pen all or any of the different objects to be produced; but as an example for a tyro, let us set about making a box in cocus or blackwood, or even boxwood, which is sufficiently good to practice upon in case of a failure, which is not at all improbable at the commencement. The box is about three inches in diameter, the lid having been faced over with a fixed tool in the slide-rest. Remove the tool, and in its place substitute the eccentric cutter, set out the eccentricity about one-half an inch and it describes a circle of one inch. Use the 96 division on the dividing-plate, place in the eccentric cutter a double angle tool of 35°, and cut deep enough to bring the pattern up sharp, and what is called the "barley corn pattern" will be the result, and if well executed, cannot fail to be satisfactory to the operator. So far so well; but this will not be enough to cover the surface of the box-lid. About $\frac{1}{8}$ of an inch from the inner side of the pattern place a row or circle of beads, which must be done with a bead-drill, and in the centre cut another eccentric pattern, and we think a very pretty effect will be obtained. We need scarcely say that the style of pattern, although done with the same tool, may be altered to almost any extent. Having finished the lid of the box, which is, or should be, fitted on the bottom, instead of a chuck, the side or cylinder part must be turned, and a very good illustrative pattern is that produced by the vertical cutter, thus: Set out the radius of tool to cut about a 2-inch circle, and then cut until the cut represents about $\frac{3}{4}$ of an inch, and take such a division on the plate that will bring each edge up to a sharp point. Having cut all round, take, say, two divisions on the plate, and move the slide-rest just the width of the tool, and cut again, using the same division, only starting two in advance of the previous cut; repeat this the length of the box, and another very effective result is obtained, and it will appear in a spiral form. This pattern is usually called the basket pattern. When this is done, the lid may be removed and the inside of the box turned out. When this is accomplished cut off the bottom, turn a boxwood chuck to fit it, and so hold it while the base of it is turned flat, and by way of practice another pattern may be cut upon it.

To be continued.

Editorial Notes.

Our Amateur Workshop.

IN the present number we publish the first of a series of papers, which are to be continued, entitled: "Three Amateur Workers—And What They Did." The object of these papers will be to show the young reader how to care for and use edge tools, and to give easy lessons in the art of making kites, æolian harps, hand-sleighs, small wagons, hanging cabinets, girl's work-boxes, doll's furniture, and a hundred other things that clever little folks *can* make if they receive a little help. Little girls will also find many things in these papers that will both amuse and instruct them, as a play-house, furniture, dolls and all, will be introduced. Foot lathes, scroll saws, and what can be done with them, will be talked of and discussed.

Correspondence.

Preserving Flower-Stakes from Rot.

Ed. Young Scientist.—Nothing is more annoying than to find, after a strong wind, some of your finest flowers blown down because the stakes have rotted off at the surface of the ground.

I have now in my possession flower-stakes which have been in constant use for over nine years, and their points are yet perfectly sound and good. I take common coal-tar and bring it to the boiling point in a kettle some 10 to 12 inches deep; I then place the lower part of the stake in the boiling tar, immersing it as deeply as the pot will allow. After they have remained therein about ten minutes, I take them out, allow the surplus tar to drain off, and roll the tarred portion in clean sharp sand, covering

every part of the tar. After they have become perfectly dry, I give them another coat of tar, completely covering the sanded part. Then, after being thoroughly dried, they will last for years. Some of them I have painted three times with lead and oil paints on the upper part, and they are ready for the fourth, while the lower portion is still sound and good. To treat a lot of stakes in this manner costs but little and pays well, as it saves a great deal of future labor and annoyance. H.

He'll Never Set the Thames on Fire.

Very few know the origin of this common phrase. Many years ago, before machinery was introduced into the flour mills for the purpose of sifting flour, it was the custom of the miller to send it home unsifted. The process of sifting was done thus, but principally in Yorkshire: The temse, or sieve, which was provided with a rim which projected from the bottom of it, was worked over the mouth of the barrel into which the flour or meal was sifted. An active fellow, who worked hard, not unfrequently set the rim of the temse on fire by the force of friction against the rim of the flour barrel, so that in fact, this part of domestic employment became the standard by which to test a man's will or capacity to hard work; and thus of a lazy fellow, or one deficient in strength, it was said, "He will not set the temse on fire." The long disuse of the word "temse" for sieve, as well as superseding of hand labor by machinery in this particular species of work, may possibly have tended to the substitution of sound for sense, in such phrases as "He will never set the Thames on fire," the North River on fire, or any other river.

Coloring Ivory and Bone.

To Color ivory or bone red, take 4 grms. of picric acid, and dissolve in 250 grms. of boiling water; add, after cooling, 8 grms. of liquid ammonia. Dissolve also 2 grms. of crystallized fuchsine (magenta) in 45 grms. of alcohol, dilute with 373 grms. of hot water, and next add 50 grms. of ammonia. As soon as the red color of the magenta solution has disappeared, the two solutions are mixed together, making a bulk of liquid amounting to about one-half litre, which is a sufficient quantity for dying from four to six sheep's skins. Ivory and bone should be placed in very weak nitric or hydrochloric acid first, before immersion in the ammoniacal liquid; wood can not be dyed by this liquid unless it has been previously painted over with paste made from flour. When to the ammoniacal liquid some gelatine solution is added, it may serve as a red ink, which does not attack steel pens. By varying the proportion of magenta and picric acid the tints obtained may be varied from a blueish red to a bright orange red. The desired colors do not appear until the ammonia is evaporated. This solution may be used for either ivory, bone, or horn.

Practical Hints.

Artficial India Rubber.—It is said that a cheap and useful substitute for India rubber is prepared by mixing a thick solution of glue with tungstate of soda and hydrochloric acid. A compound of tungstic acid and glue is precipitated, which at a temperature of 86° to 104° Fahrenheit, is sufficiently elastic to admit of being drawn out into very thin sheets, which, on cooling, become solid and brittle, but on being heated again, soft and plastic. It can be used for many of the purposes to which rubber is adapted.

A Forgotten Color.—The simple decoction of onion-peel is said to produce upon glove-leather an orange-yellow superior in lustre to any other. It is also said to be suitable for mixing with light bark shades, especially willow bark, and as a yellow for modulating browns. The onion-dye is said to fix itself readily, even upon leathers which resist colors, and covers them well and even. Dr. Reimann seems, however, almost as sceptical of the tinctorial power of onions as of truffles.—*Chemical News.*

Glass Cement.—A cement to stop cracks in glass vessels, to resist moisture and heat, is made by dissolving casein in a cold saturated solution of borax. With this solution paste strips of hog's or bullock's bladder, softened in water, on the cracks in the glass, and dry at a gentle heat. If the vessel is to be heated, coat the bladder on the outside, just before it has become quite dry, with a paste of a rather concentrated solution of soda and quicklime, or plaster-of-Paris.

To Harden Plaster-of-Paris.—By adding 3 to 4 per cent. of powdered marshmallow root to plaster-of-Paris, the resultant mass, in about an hour after setting, will be found to have acquired such a degree of hardness that it may be sawed, turned, etc. Prepared in this way, the plaster is found to afford an excellent substitute for bone or ivory in the manufacture of buttons, dominoes, dice, etc. If the amount of marshmallow is increased to 8 per cent., the mass acquires such hardness that it may be rolled out into thin plates, which may be painted, polished, and varnished.

Tool Chest.—The chest should be long enough to take a ripper-saw inside the saw-till, say 29 inch clear. A good plan is to rip the boards down and glue and tongue them, heart-edge and sap-edge together. The tills may be made of yellow

pine. Oak, which is sometimes used, is heavy, and seems to have a tendency to rust the tools. The runners may be of oak or other hard wood, capped with whalebone. Pine is most suitable for the tills if the maker intends to veneer the inside.

Black Coating for Zinc.—Dingler's *Polytechnic Journal* states that M. Neumann has instituted a series of experiments to point out the best material to produce upon statuary or ornamental objects made of zinc a pleasing blackish coating, without impairing the effect of the natural color of the metal, as would be the case when an oil paint or varnish is used. The best results were obtained when nitrate of protoxide of manganese was employed. This salt, on being heated, is decomposed, yielding black peroxide of manganese, and the degree of heat required is not so high as to affect the zinc. The best solution for this purpose is fifty-four grammes of the salt in one litre of water.

Preservation of Paste with Salicylic Acid. The souring and molding of paste used by bookbinders and workmen in other trades, which, according to circumstances, occurs in about two or three days, may be entirely avoided, according to the statement of Herr P. Lung, by the addition and thorough mixture with the freshly-prepared paste of a few drops of salicylic acid. When thus treated, a paste may be kept for weeks in a heated room without losing its freshness, and even when it has by long standing become dry and tough, may be at once rendered fluid and serviceable by treatment with hot water. The addition of the acid does not, according to this author, affect the stickiness of the paste to any sensible degree. The above item will, doubtless, prove serviceable likewise to all who have only occasionally to make use of paste.—*Gewerbeblatt aus Wurttemberg.*

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa.

I have a four-legged and four-winged one-headed chicken, in alcohol, which I should like to exchange for a good breech-loading shot gun, or for standard scientific books. A. H., Box 500, Albion, Ohio.

Wanted, scientific books, minerals, fossils, and Indian relics, in exchange for minerals, fossils, coins, old Continental and Federal money over one hundred years old (very rare), foreign stamps. A. W. Baily, Box 712, Atlantic City, N. J.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Idaho Mineral Specimens, for bound books on science, travels, history, biography, political, masonic, and others that are instructive. J. P. Clough, Junction, Lemhi Co., Idaho.

I have minerals (including fossils and dentrites), to exchange for minerals; also a papyrograph outfit, without press (worth $25), for offers. W. H. Eastman, Hyde Park, Mass.

Craig's Simple microscope and three objects, $2.50; 155 rare stamps in small album, 1 font of type; "Illustrious Mechanics," $1; "Northern Lights," $1.50; for coins and curiosities. Geo. K. Fischer, 729 North 6th St., Phila.

Klose's celebrated "School for the Clarionet," new, $3; will enchange for telescope, microscope, piccolo, books, or offers. Rush Holbrook, Wonewoe, Juneau Co., Wis.

One or two handsomely mounted red deer heads, attractive ornaments for any dining-room or hall, for microscope, telescope, sporting implements, camping outfit, scientific books, or offers. R. B. Hough, Lowville, Lewis Co., N. Y.

A new E-flat solo cornet, cost $22, for a self-inking printing press and outfit of same value and condition, also B-flat clarionet, books, papers, magazines, etc., for offers, C. W. Hughes, P. O. Box 96, Shreve, Ohio.

Hope's Manual of Sorento and Inlaid Work, cloth edition, price $1.25; would like to exchange for books on aquaria postage stamps, hammocks, or almost anything. G. Keppel, Zeeland, Ottawa Co., Mich.

A new one horse power horizontal steam engine, in complete running order, worth $60, for a first class coal stove, watch, or offers. Geo. L. Lamson, La Fargeville, Jeff. Co., N. Y.

A handsome Young America self-inking printing press, chase 3½ x 4¾ inch, with 5 founts of type, 300 cards, and outfit complete, for a good wood-turning lathe, or offers. E. McLean, 443 Clermont Ave., Brooklyn.

Telescope, microscope, drawing instruments, and other things, in exchange for printing press and outfit, or offers; wanted, cards, type, etc. Ewing McLean, Greencastle, Ind.

I should like to exchange birds eggs with any one living in the far West, South, or in foreign countries. Wallace Ross, Lock Box 97, Rutland, Vermont.

I have some good specimens of Pentremites from the sub-carboniferous formation, that I would like to exchange for books. H. Russell, Grassy Cove, Cumberland Co., Tennessee.

Bonanza printing press, with three fonts of type, and assortment of blank cards; value of outfit $7.25; would like rifle, books, or offers. Geo. R. Simpson, Janesville, Bremer Co., Iowa.

Fine cabinet for sale or exchange; polished walnut and maple, 27 drawers, 3 closets, all locked; 7 ft. x 5 ft. x 19 inches; for any kind of specimens. W. W. Stockton, Box 190, West Chester, Chester Co., Pa.

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, OCTOBER, 1880. No. 10.

Cheap Lathes and How to Use Them.

A RECENT writer on Amateur Mechanics tells us that Turning is "beyond all doubt the chief of the Amateur Handicrafts," and no one whose judgment is of any value will dispute it. Fortunately, at the present day cheap lathes are quite common. Some years ago no lathe in market was sold for a less price than $50 to $100; to-day, we have many that range as low as $5, and yet are capable of doing valuable work. Some time ago a friend of ours had one of these cheap lathes given to him. He showed it to an acquaintance who was a first rate mechanic, and was advised to send it to the junk shop as being good for nothing. On receiving such advice, he naturally felt that the art of turning was not an occupation for him, and he was about to get rid of his seemingly worthless present, when he happened to meet another friend, who, fortunately, was quite as skillful, but not quite as "aristrocratic" in his mechanical ideas. This friend spent an evening with him, put the lathe together, and adjusted it, fixed the tools and sharpened them up. He then took a piece of common wood, which he found amongst the firewood, sawed it rudely into shape, put it in the lathe, and in a few minutes he turned out a handsome little vase, which he presented to the astonished wife of his host, and it now stands on her mantelpiece as one of her choicest ornaments. Her husband, meantime, stood looking on in amazement; he had been told that his lathe was fit only for the the junk shop, and here was a quiet, unobtrusive man using it to make articles of great beauty, such as vases for the mantel-piece, and of usefulness, such as handles for tools, etc. Next day, when he went down town, he wrapped the smoothly turned and finely polished vase in soft white paper, and took it with him. He showed it to his aristocratic friend, told him it was a present he had just received,

and wanted to know what he thought of it. The friend thought it beautiful, and praised the skill of the workman. After some further chatting, it was agreed between the friends that the man that turned that vase must not only be a good turner, but he must have a good lathe. When it leaked out that the vase had been turned in the cheap and "worthless" lathe, the reply was: "Well, he may have turned that thing in it; anybody could do that, but he cannot turn anything that is really worth turning!" The owner of the lathe had nothing to say to this. If it would turn such simple things as vases, handles, brass knobs, and screws, and the thousand and one little odds and ends, which every amateur mechanic needs, it would serve his turn very well *until he could get a better*.

We relate this anecdote, which is true in every particular, for the purpose of teaching our young readers that these cheap lathes are good and useful tools, and that they may be used to very good advantage for many kinds of work. It is true that there are many things which are beyond their reach, but this is also true, to a certain extent, of far better and more expensive lathes.

It is not very difficult to learn to use these simple lathes. Turning is an art not so easily learned as fret sawing, planing and many other departments of amateur handicraft. But it is easier to learn to use the lathe than to learn to use the file, or the art of the cabinet maker; and small work does not require any greater exertion of strength than is needed for operating the sewing machine. Hence, turning is an art which is well adapted to the use of girls as well as boys, and which is often quite as useful to them as we shall show hereafter.

During the past ten years, cheap lathes have become quite common, but, unfortunately, while we have simple books on amateur scroll and fret sawing, on engraving, and other arts, the only books on turning that we know of, are beyond the reach of boys and girls, from the simple reason that the lathes described are too expensive, and the work is of a higher grade than most amateurs have the skill to turn out. We propose, therefore, in our next twelve issues, to give a series of articles which we hope will enable our readers to acquire a respectable degree of skill in this delightful art.

We shall not enter into the intricacies of oval and eccentric chucks, but we can easily teach them how to use the common tools, and to turn up such pieces of brass, iron, wood, bone, ivory, etc., as are used in the making of ordinary apparatus and the performance of common experiments.

Three Amateur Workers—and What They Did—II.

BY FRED. T. HODGSON.

It took Mr. Carpenter some time to decide whether he would buy good tools, and pay a fair price for them, or buy cheaper ones; being a sensible man, however, he avoided the mistake of buying poor tools because they are cheap. He purchased good tools, not fancy or flashy ones, but such as could be depended upon to do good work with, when properly handled; and here let me say to parents and others who buy tools for young folks, that it is very unwise to purchase inferior tools, for the trained and skilled artisan finds it almost impossible to make a good job with them, and how much more difficult it must be for a young amateur to make respectable work with such inferior appliances.

A sufficient number of tools for present purposes was bought, and ten dollars were expended for a load of dry lumber, of such dimensions and quality as he thought would be most useful.

A space in the stable, that had been used for storing away a lot of useless furniture, stoves, pipes, and other things, was cleaned out, and a very respectable workshop, about twelve by sixteen feet, was marked off, and given over for the boy's use. This, of course, made a much larger workshop than was necessary, but Mr. Carpenter thought, as he had the room to spare, that it would be as well to make it large.

The boys had evidently hurried home from school, for they arrived earlier than

usual, and immediately hastened to the stable to see the tools and lumber their father had bought; and Ellwood fairly yelled with delight when he saw the brightly polished saws, chisels, and bits. He had a thousand questions to ask concerning the tools, and so rapidly were they put, that before his father could answer one, two others were asked. "How much did you give for the four saws, Pa?" said Ellwood. "I gave five dollars and a quarter for them, but I believe they are worth more, or at least more is asked for them if they are bought singly, but, you see, I bought a number of other tools in the same store, and got them a little cheaper on that account," said Mr. Carpenter. "What do we want the two big saws for?" said the boy. "Why," said Mr. Carpenter, "One of them is for cutting boards across the grain, and is called a 'cut off' or cross-cut saw, and the other one is for cutting boards lengthwise or with the grain, and is called a rip-saw; you will notice that it has much larger teeth than the "cross-cut" saw, and that the teeth have more "hook," and are filed square across. Four teeth to the inch is about the average for a rip-saw, and eight to the inch for a "cross-cut"* The

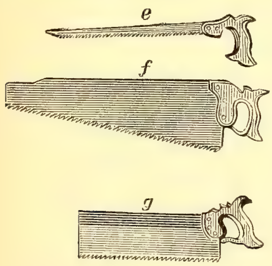

Fig. 1.

small saw with the iron rib on the back, is called a sash saw, by some workmen, by others it is called a "tenon saw." This last name is the proper one, and I wish you to remember that. The tenon saw has about fourteen teeth to the inch, and is filed very nearly the same as a cross-cut. The long narrow saw is called a "compass saw," and is used for cutting circles from four inches to two or three feet in diameter. It has about the same number of teeth to the inch as a "cross-cut saw," but is filed squarer across the tooth, but not so square as a rip saw. There are quite a number of other kinds of saws than the ones I have bought, but we do not require them at present, when we do I will get them and describe them and their use, so that you will know what they are for and how to work with them."

"Come boys," said Mr. Carpenter, "we must now go to work and make a carpenter's bench and two saw horses. Ellwood, you bring into the shop one of those pieces of scantling that is 2 by 4 inches."

"What do you mean, Pa, by 2 by 4 inches?" said Ellwood.

"I ought to have explained this matter before, my son, but it is not too late yet. Two by four inches means any piece of wood or other material, or space, whose dimensions are two inches on two sides, by four inches on the other two sides, regardless of length. All scantlings and timbers are measured this way, so that you will know after this what is understood when timbers or scantling are spoken of as being 2 by 4 inches, 4 by 6 inches, 3 by 10 inches, or any similar dimensions. Well, this being explained, let us proceed to work. We want four legs or standards for the bench, and eight legs for the two saw horses. Legs for the saw horse must be cut twenty inches long; you will see the 20 figured on the rule (Fig. 2). Be careful and have the legs all cut to one length. Now we want two top pieces for the horses, cut from the same kind of scantling. They want to be two feet six inches long. Now then, lay all the legs in a row close to each other with the ends all in line; now lay one of the top pieces flatwise on the legs with one of its edges on the line of the ends of the legs, then mark with a lead pencil along the other edge, on the legs, and we have a line cutting across the flat sides of the

*f, Shows the shape and style of both cross-cut saw and rip-saw. The cross-cut saw generally has a blade about twenty-four inches long. The rip-saw blade is about twenty-six inches long.
g, shows a tenon-saw with a blade about sixteen inches long.
e, shows a compass saw with a blade about twenty inches long, and about one inch wide in the centre.

legs at four inches distant from the ends, from this mark take off the wood, leaving the end about one inch thick. This will give the legs the right 'spread.' Nail the

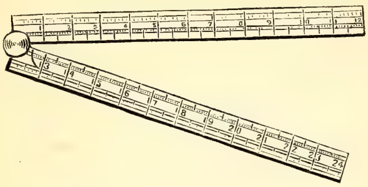

Fig. 2.

tapered ends of these legs fast to the top-pieces, and about three inches clear from the ends of the latter. When this is done, and the horses are solid on their legs, nail short inch boards across the legs with the upper edges put close under the top

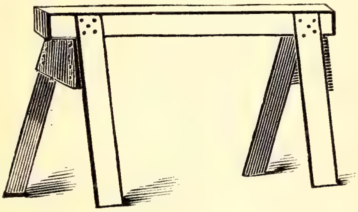

Fig. 3.

pieces. These pieces act as braces for the legs, and supports for the top pieces. Now, boys, we have two good saw horses. here is one of them shown in Fig. 3. You have done well!"

"Now then for the workbench! We want four legs cut off, two feet four inches long, and made of stuff 4 by 4 inches. Two feet six inches—which will be the height of the bench when completed, on account of the two inch top—is rather too high for you boys, but, as I may want to use it myself sometimes, it is better made high enough now, and you boys can put a plank on the floor when you want to use the bench to raise you high enough to work with ease.

The legs being cut, it is now necessary to cut the cross pieces or bearers. We want five of these: they require to be one inch thick, twelve inches wide, and three feet long. Mind and cut them off square at the ends, and have them all exactly of the same length."

"There, children, I think that will do for this evening, we will complete the workbench to-morrow evening, after you arrive from school."

The boys were anxious to keep at work, but Mr. Carpenter told them that it would be best not to do too much at once, or they might get tired, and not care to work at all.

(To be continued.)

A Breakfast for a Whale—What it Was, and How it was Got—II.

BY A. W. ROBERTS.

Concluded from page 103.

FIRST I visited the "Captain's," and eat as hearty a meal as I could, for I began to suspect that I had some hard work before me. Then to Pyne's, to read up on white whales; and after that to the Fulton Market fish stands, to find out the nearest fishing station, and if I could reach it in time for a catch.

The first man I spoke to informed me that Barnum's folks had been to the market that morning, trying to obtain a hundred pounds of live eels, but that at that season of the year all the eels came to the market packed in ice. I asked why other kinds of fish were not just as good as eels, and he informed me that eels were best, because they lived a long while, and had soft fins, whereas a sea bass or black fish would be apt to stick in the gullet of a whale and choke him. This agreed exactly with the conclusions I had reached up to this time. I gave him a cigar and several passes to the museum, and then asked more questions. I found that the nearest fishing station was Unionville, Gravesend Bay, and that Ed Morris was the most reliable man to go to; that the tide was in my favor, and that I would be in time to catch the stage from Greenwood to the bay.

When I reached Greenwood the stage had gone. After a long talk, I coaxed (with money) one of the cemetery hackmen to drive me at full speed to Unionville.

My heart fairly bounded as I passed

through this pleasant little hamlet, at the sight of the tarred netting hanging on every fence, and I felt that success would be mine. I found Ed Morris, who sent out runners to all the eel pot fishermen to secure every eel. After hiring a man and a boat, and instructing him to secure all the lafayettes and codlings from the three nearest fish traps, and telling them to fill the boats with water to keep the fish alive till reaching the shore, Morris and I started for the fourth "pound" or "trap," with an extra boat to bring in all the live fish obtainable. I had never seen a "pound" lifted before, and when I saw the great solid moving masses of many varieties of fish I became silent. It would be difficult to exaggerate the effect produced on my mind. It was not merely respectful attention—it was the passionate enthusiasm which a sensitive person shows when brought in contact with the new, strange, and irresistible influence produced by Nature's great works.

Returning to the shore I began to arrange the boats for the voyage to New York. Four boats were hired to transport the live fish in, and five small boys to sit at the bow of each boat to bail water in and out. I and the fifth boy were extras to relieve the others when tired.

I had much trouble to obtain the tin cans, there being no tin store in the village, and the fishermen's wives disliking to part with their tinware; but by offering double the value, I managed to obtain six pails. This gave me two extra ones, in case my bailers lost any overboard.

All the boats were now in with their cargoes of live fish in excellent condition. These boats were connected together with strong towing ropes, some twelve feet apart, and these were to be attached to the towing sail boats.

The tide by this time was rolling in fast; and noticing that one of the boats was in danger of being swamped, I dashed into the water, clothes and all, and by rapid swimming reached the boat before the fish escaped. Up to this time the many fishermen assembled on the beach, watching this curious exhibition, had fought shy of me, evidently thinking I was a Broadway fisherman; but when they saw those stylish pants and boots swim out, they seemed to accept me as a true water dog. The package of passes were well soaked, so I distributed them to the fishermen as peace offerings. The previous jesting remarks that the young fishermen had indulged in ceased after this, and strong brown arms were ever ready to haul, pull, and help in every way.

The boats containing the live fish were covered over with netting, except at the bow, where a small space was left for the boy to sit, who was to bail water in and out. Each boy was instructed that in case his boat filled, he was to jump overboard, and relieve the boat, until she could be lightened, by bailing out water.

All was now ready for the start. Two of the largest market sail boats were hired to tow the four boats of fish, which, when strung out in line, presented a very odd appearance, with a boy sitting in each boat bailing water. It took me some time to find part of my clothing, as I could not remember where I had thrown them off during the excitement, but I recovered all but my kid gloves, handkerchief, and necktie.

It was now late in the afternoon. The tide being in our favor, and a fair wind, we ought to reach the city in good season. So, going on board of one of the sail boats, we sailed out of the bay amid cheers and showers of dead fish. All went well till we got past Fort Hamilton, when a tug boat suddenly crossed our bows, and we were forced to take her swash. One of the boats filled immediately, but the bailer was overboard in an instant, and she righted. Jumping overboard, I passed down to the boat that had filled, and helped the bailer to lighten her up. All the fish were doing well, showing no signs of distress.

It now being about tea time, each boy was relieved to come aboard the sail boats and take a hearty meal which I had provided. While I was taking my tea, one of the boys filled his boat too full, and she swamped; and the boy, in jumping, nearly turned her over on top of him, on account of his holding on to the gunwale of the boat, when he ought to have grasped

the tow line. In an instant I was overboard and righted the boat. On we went, hugging the inshore, to keep clear of passing vessels, amid cheers and salutations from shore and dock. I was overboard quite often, but being perfectly at home in the water, I did not mind it much. The only part of the voyage I feared was the ferry boats, when we reached New York city. Fortunately, the teams and hogsheads to take the fish to the Museum were to be in waiting at Castle Garden.

When rounding Governor's Island, I espied one of those hugh black tug boats heading right for us. We dared not run across her bow for fear she would run us down; so there was nothing left to do but to wait until she passed us, and take her swash. In a few seconds after passing, we could see the big rollers heading directly for us. In an instant all four boats filled; overboard I went, but a big wave caught me, carrying me some distance past the boats. I could see one of the boats bottom up, and I made up mind that one lot of fish had escaped. With most vigorous swimming I seemed to gain but little on the sail boats; but at last they lowered sail, and I overtook them. With the aid of all the boys we managed to right the capsized boat, and, to my astonisment, all the fish were safe. The netting had saved them.

No accident occurred after this, and we reached Castle Garden in safety, and in a short time the fish were on the way to the Museum.

There, in the huge tank, lay the white whale in a pool of water, squealing like a young pig. (They make a peculiar squealing noise when out of water.) The live fish were carefully lowered into the water, and with the eels made a great show. The fishermen and boys who helped me through, visited the Museum through the day, and gave Barnum and my Eastern friend a vivid account of my hardships and adventures, so that in their estimation I was a great fisherman.

Reaching home at four o'clock in the morning, I awoke my mother, and told her all of my adventures, and when I came to the lost and spoiled clothing, I could not help but exclaim: "Why! mother! nobody knows the trouble I've been through, just to obtain a supper for a whale."

This was my first great lesson in "Do fish feed by suction?" How often I have heard that word used by dealers when a customer asked, "Did the fish need feeding?" Their answer was "No, ma'am, they exist on 'suction,' or what is in the water." And there are thousands of people at the present day who still hold that fish live on "suction." I know of a person who has had charge of thousands of fish living in aquaria, and who up to two years ago argued that he had made an especial study as to how often fish required food, and that he *knew* they could live without food for long periods of time, and not look or be any the worse for it. I was once connected with an establishment where this theory was firmly established—that the fish needed to be fed only two to three times a year. The fish were in a most wretched condition, many of them so weak that in attempting to swim they wobbled from side to side. The crabs were chewing each other up. I have seen the lobsters lay on their backs all night, snapping with their claws at the fish above them. Even for months the toughest and most hardy of fish were dying every day. At last I begged of the proprietor to allow me to feed the fish. The first day I gave them five hundred clams, twenty pounds of beef, ten pounds of fish, large quantities of ulva and enteromorpha for the vegetable feeders, one half bushel of snails, and four quarts of shrimp, and I could have fed out double the quantity. That night I examined the lobsters—they were all in bed and not snapping and clawing at their neighbors. The black fish, who, previous to this feed, had the wobbles so bad, and were afraid of being eaten up by each other, now had both strength and courage to come forth and form into a school that went circling round and round the immense tank in beautiful style. The star fish gave up cannibalism and took to eating the snails. The sea urchins and hermit crabs devoured immense quantities of the enteromorpha.

When collecting on the Massachusetts coast, I often visited the fishing smacks, for the purpose of examining the contents of the stomachs of various kinds of fishes. I always found them packed solid with food. Why do fish go to all the trouble of eating the different kinds of fish if it is not for some good purpose—to sustain life. Why have they teeth if they are not of any use?

When at Barnum's, the fish were fed at three o'clock; at that time they became uneasy, and at the first stroke of the chopping knife on the feeding board, every fish was to the front of his tank, often pressing their noses against the glass. The crabs would become frantic and scramble all over the rockwork, searching for their food. Our greatest anxiety with new fish was to get them to feed, then we considered they were out of danger.

Alfred Lloyd, of the Crystal Palace Aquarium, London, who, I consider, is the very best authority on aquaria, feeds to the animals contained in the tanks thousands of pounds of food yearly, consisting of thirteen kinds—both animal and vegetable.

Home-made Telescopes and Microscopes.—X.

NEW FORMULA FOR A MICROSCOPE OBJECT-GLASS BY MR. WENHAM.

A PENCIL of rays exceeding an angle of 40° from a luminous point cannot be secured with less than three superposed lenses of increasing focus and diameter, by the use of which combination rays beyond this angle are transmitted, with successive refractions in their course, towards the posterior conjugate focus. Until quite recently, each of these separate lenses has been partly achromatized by its own concave lens of flint-glass, the surface in contact with the crown-glass being of the same radius, united with Canada balsam; the front lens has been made a triple, the middle a double, and the back again a triple achromatic. This combination, therefore, consists of eight lenses, and the rays in their passage are subject to errors arising from sixteen surfaces of glass.

In the new form there are but ten surfaces, and one concave lens of dense flint is used for correcting four convex lenses of crown-glass. As this might at first sight be considered inconsistent with theory, a brief retrospect of the early improvements of the microscope object-glass will help to define the conditions. The knowledge of its construction has been entirely in the hands of working opticians; and the information published on the subject being scanty, this has probably prevented the scientific analyst from giving that aid which might have been expected.

Previous to the year 1829 a few microscopic object-glasses were made, composed of three superposed achromatic lenses; but this combination appears to have been used merely with the intention of gaining an increase of power in ignorance of any principle, and without even a knowledge of the value of angular aperture.

At this time the late J. J. Lister tried a number of experiments, and discovered the law of the aplanatic focus, and proved that, by separating lenses suitably corrected, there were one or two positions in which the spherical aberration was balanced. This was explained in a paper read before the Royal Society in 1829. In the year 1831 Mr. Ross was employed to construct the first achromatic object-glass in accordance with this principle, which performed "with a degree of success never anticipated."

Mr. Ross then discovered that, after he had adjusted the interval of his lenses for the aplanatic focus, that position would no longer be correct if a plate of thin glass was placed above the object; this focus had then to be sought in a different plane, and the lenses brought closer together, in order to neutralise the negative aberration caused by covering-glass of various thickness. From this period the "adjustment" with which all our best object-glasses are now provided, became established. Fig. 14 is the form of object-glass used at this time, consisting of three plano-concave achromatics, whose foci were nearly in the proportion of 1, 2, 3.

No greater angle than 60° could be ob-

tained with this system in an $\frac{1}{8}$ objective (the highest power then made) for reasons apparent in the diagram. The excessive depth of curvature of the contact-surfaces of the front pair is unfavorable for the passage of the marginal rays; the softness of the flint-glass forming the first plane was also objectionable. In the year 1837 Mr. Lister gave Mr. Ross a diagram for an improved "eighth," having a triple front lens in the form shown in Fig. 15. By this the passage of extreme rays was facilitated; and in order to diminish the depth of curvature, a very dense glass was used, having a specific gravity of 4·351. Faraday's glass, having a density of 6·4, had been previously tried, but was abandoned on account of a difficulty in working it. The polished surfaces of both these qualities of dense glass speedily became tarnished by exposure to the air; and thus the dense flint concave could only be employed in a triple combination, that is, when cemented between two lenses of crown-glass: this form of front was kept a trade secret, and was not published in any work treating of the optics of the microscope. The front incident surface of the flint of the middle pair was made concave in order to reduce the depth of the contact; and for this reason only, as that surface has but little influence in correcting the oblique pencils, or in producing flatness of field, and may be a plane with an equally good or better result. "Eighths" of this form with angles of 80° were made, and remained unaltered till the year 1850, when larger apertures were called for, and Mr. Lister introduced the triple back lens.

The necessity for this will be seen by the diagram in Fig. 15, which shows that the contact-surfaces of the back achromatic are too deep, thus giving great thickness to the lens and limiting its diameter; dense flint would have remedied this to some extent; but its liability to tarnish rendered its use in a pair objectionable. The highest density at this time known, quite free from this defect, was 3·686. By means of the triple back, the final corrections were rendered less abrupt, a greater portion of the marginal rays could be collected, and the aperture of an "eighth" was at once brought up to 130° or more.

At this time the author (Mr. Wenham) had been making some experiments in the construction of an object-glass in the form of Fig. 15. Mr. Lister having favored his "eighth" with an examination, was good enough to communicate his late improvement of the triple back. No time was lost in giving this a trial, the result of which proved that excessive negative

Fig. 14. Fig. 16.

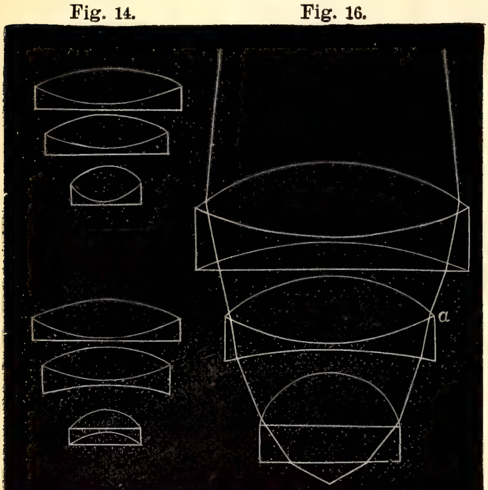

Fig. 15.

Fig. 17.

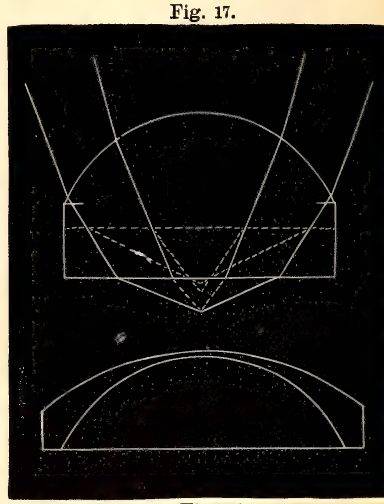

Fig. 18.

aberration or over-correction could readily be commanded with lenses of shallow, contact curves. During these trials all chromatic correction was obtained by alterations in the triple back; for it was found that the color-correction could not be controlled by a change in the concave surface of the triple front, as the negative power of the flint here appeared to be feeble, requiring a great difference in radius to give a trifling result. For this reason the front concaves were formed of very dense and highly dispersive flint; the cause of this was analysed by a large diagram, with the passage of the rays projected through the combination, starting from the longest conjugate focus at the back. This proved that the rays from that focus passed through the concave flint of the front nearly as a radius from its centre, or in such a direction that its negative influence was almost neutralised. It is well known that a lens may be achromatic for parallel rays, and under-corrected for divergent ones. The utmost extent of this condition was apparent in the object-glass under consideration.

This led the author to the idea of the single front lens of crown-glass, which gave a fine result at the first attempt, as the back combinations to which it was applied happened to have a suitable excess of negative or over-correction existing in the triple back alone, the middle being neutral or nearly achromatic. Still there was a defect remaining as positive spherical aberration; and this was afterwards cured by giving additional thickness to the front lens, which is now recognized as a most essential element of correction. In a "fifteenth," for instance, a difference of thickness of only ·002 of an inch will determine the quality between a good and indifferent glass. Fig. 17 represents a front lens suitable for bringing the back rays to a focus. The dotted lines indicate the effect of this difference, showing that with a lens of less thickness the marginal rays fall within the central, producing positive aberration as the result.

The single front introduced by the author (Mr. Wenham) is now used by every maker: for several years he could not induce opticians to change their system, though challenged by a series of high powers constructed on this formula for the purpose of proving its superiority. Fig. 16 represents the curves of the first successful "eighth" on this system, having an aperture of 130°, enlarged ten times. On tracing the passage of the marginal rays through the combination, it will be seen that, though the successive refractions are nearly equalized, the contact-surfaces of the middle pair are somewhat deep, though no over-correction existed or was needed here, for this would have required a shorter radius still (the density of the flint in this was 3·686). If this pair of lenses was not cemented with Canada balsam, total reflection would take place near the circumference of the contact flint surface, cutting off the marginal rays at *a*, and limiting the aperture. It might be argued that practically this would be no disadvantage, as these surfaces are united with Canada balsam, whose refraction is higher than the crown; so that the rays in this case must proceed with very little deviation. But incidences beyond the angle of total reflection may be considered detrimental, as they imply excessive depth of curvature; this can be discovered by looking through the front of an object-glass held close to the eye, any air-films in the balsam near the edge of the lens appearing as opaque black spots.

Science in Common-Place Things.—The Syphon.

IN our previous issue we stated that the author of "Physics Without Apparatus" not only used special apparatus in his experiments, but that in some cases he employed apparatus which could be procured only from dealers in philosophical apparatus. The engraving which we give this month, representing the well-known Cup of Tantalus, fully sustains this position. The Cup of Tantalus is, however, an illustration of such a useful instrument, that a short description of it will prove interesting and useful.

Many of our readers have probably read the story of Tantalus, whose name is embodied in our language in the word *tantalize*. Various accounts are given of the

reason for his punishment, and its form, but the one from which the common idea is derived is that of Homer, in whose poem (The Odyssey) Ulysses tells the Phæacians that in the lower world he had beheld Tantalus standing up to the chin in water, which constantly eludes his lip as often as he attempts to quench the thirst that torments him. Over his head grow all kinds of fruits ; but whenever he reaches forth his hand to take them, the wind scatters them to the clouds.

Our engraving represents the figure of Tantalus stooping down to drink the water which reaches almost to his lips, but as soon as the water rises to the level, A B, the concealed syphon, C, which is shown in dotted lines, begins to act, and the water immediately sinks just as it is about to rise within his reach.

The syphon is one of the most useful pieces of apparatus that we have, either in the hands of the amateur or the professional workman. It enables us to transfer liquids from a higher to a lower level, over obstacles which would otherwise cause great difficulty, and therefore it is well for our young readers to clearly understand the principles upon which it acts.

Two very distinct agencies are always at work in the operation of the syphon—the pressure of the atmosphere, and the weight of the water in the legs of the syphon. In the syphon shown in Fig. 2, the column of water in the leg, D, is longer, and consequently heavier, than the column in the

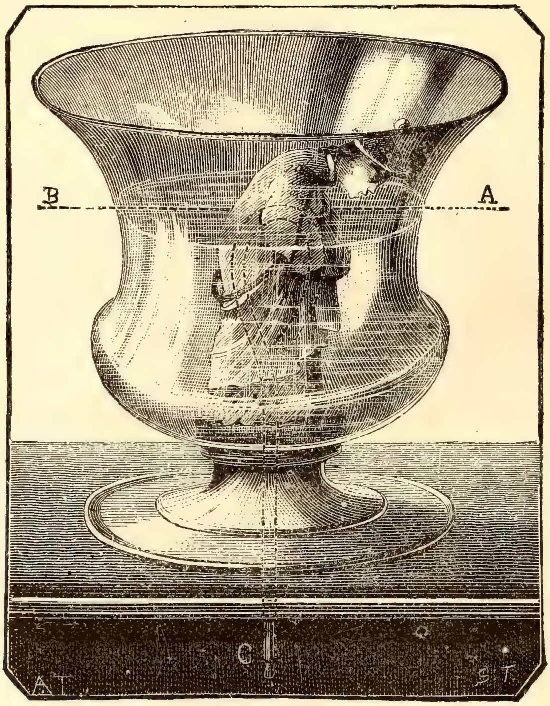

Fig. 1.—CUP OF TANTALUS.

leg E, and consequently it will overbalance it and fall down.

It is obvious, however, that the column of water from E to B is held in its position by the weight of the atmosphere pressing on the surface of the water in the vessel, A. If it were not for this pressure, the water in the syphon would separate at B, and fall down each leg, leaving the tube empty. But as fast as the heavier column in D falls down and escapes from C, the

water in A is forced up through E B to supply its place, and a constant stream is the result. It follows from this that under ordinary circumstances the point, B, cannot be raised more than thirty-two to thirty-four feet above the surface of the liquid in A.

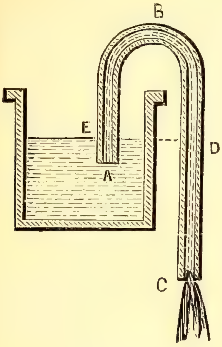

Fig. 2.

To those who keep an aquarium, the syphon is not only a useful, but an indispensable instrument. One of the best forms for this purpose is that shown in Fig. 3. It will be seen that the legs are of

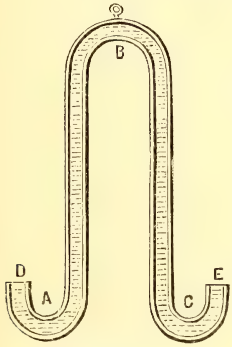

Fig 3.

equal length, and turned up at the ends. A syphon of this form may be filled and hung up on a nail until wanted, or it may be filled in a tub or tank, and then lifted out and placed in the aquarium. One of the objections to the syphon is the difficulty of starting or filling it, and this form obviates this to a certain extent. A syphon of the form shown has also the advantage that it does not disturb the sediment at the bottom of the tank, as a vertical pipe would do.

Practical Hints.

Adulteration of Coffee.—Prof. S. P. Sharples, State Assayer of Massachusetts, has been investigating the character of the ground coffee ordinarily put up in packages. He finds that peas, corn, oats, rye, etc., form the chief constituents. Fortunately he has not detected the presence of any positively injurious substances, and if people, who can easily find out the cost of a pound of green coffee, expect to buy a like quantity roasted and ground for half the price, they deserve to drink weak pea soup. For detecting adulterations he gives the following rules: "Take some cold water in a glass and throw upon it about half a teaspoonful of the coffee to be tested, stirring it around so as to wet the grains. Pure coffee will float and scarcely colors the water. Beans and chicory sink to the bottom. Chicory colors the water at once, beans more slowly. Test the part that floats by chewing it. Coffee will thus be recognized by its taste. Nut shells, which also float, are hard and brittle. A species of nut which has lately come into use strongly resembles coffee when ground up, by floating on the water as well as by its feeling between the teeth; but the difference can easily be detected, because the adulterating ingredient is nearly tasteless. After subjecting the suspected article to the above test, spread some of it out on a sheet of paper and examine it carefully for grains of rye, oats, and peas. The pea ingredient will frequently be found in pieces one-eighth the size of a pea, and the rye in half grains. Chicory is tough when taken between the teeth, and has a bitter taste, different from the bitter of coffee."

The Fair of the American Institute.—The managers of the American Institute have this year made an extra effort to increase the attractiveness of the fair, and the result is highly satisfactory. As usual the fair is specially attractive to the young, and forms, indeed, a school of object lessons of the utmost value as a means of practical education. Some people, who evidently do not appreciate the value of this feature, claim that everything that is in the fair can be seen elsewhere. True, but not in the same shape or so conveniently accessible. There we see everything presented in the very best manner, so as to show its peculiarities and the mode of its operation. By all means let the young folks spend hour upon hour at the fair. At no other place can they learn so much in such a short time.

Popular Microscopy.—Prof. Starr, of Westfield, N. J., who, as a lecturer, is well-known to be one of the most successful, at least so far as interesting popular audiences is concerned, has just returned from a trip to the West, where even in these exciting times he has found interested audiences. Sabbath schools and popular associations, who wish a really interesting and instructive lecture and exhibition, would do well to correspond with Prof. Starr.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

Wanted, specimens metallic ores; will give in exchange fossil shells, Vicksburg epoch, Tertiary period; state kinds of ore. Philip Crutcher, Warren Co., Vicksburg, Miss.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing, P. O. Box 178, Wattsburg, Erie Co., Pa.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

I have some stamps which I will trade against other stamps, or offers; please send list of stamps you have to exchange. J., 226 West 22d St., New York.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J,

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

Wanted, a household microscope, telescope, large lenses, well-mounted slides for the microscope, books on the microscope or entomology, in exchange for stuffed birds or minerals; describe offers, and state what is wanted in exchange. E. O. Tuttle, Hampden, Mass.

Minerals to exchange for other minerals; state what specimens you have for exchange. Samuel Wynne, Box 54, Phoenixville, Pa.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa,

I have a four-legged and four-winged one-headed chicken, in alcohol, which I should like to exchange for a good breech-loading shot gun, or for standard scientific books. A. H., Box 500, Albion, Ohio.

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Wanted, scientific books, minerals, fossils, and Indian relics, in exchange for minerals, fossils, coins, old Continental and Federal money over one hundred years old (very rare), foreign stamps, A. W. Baily, Box 712, Atlantic City, N. J.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Idaho Mineral Specimens, for bound books on science, travels, history, biography, political, masonic, and others that are instructive. J. P. Clough, Junction, Lemhi Co., Idaho.

I have minerals (including fossils and dentrites), to exchange for minerals; also a papyrograph outfit, without press (worth $25), for offers. W. H. Eastman, Hyde Park, Mass.

Craig's Simple microscope and three objects, $2.50; 155 rare stamps in small album, 1 font of type; "Illustrious Mechanics," $1; "Northern Lights," $1.50; for coins and curiosities. Geo. K. Fischer, 729 North 6th St., Phila.

Klose's celebrated "School for the Clarionet," new, $3; will enchange for telescope, microscope, piccolo, books, or offers. Rush Holbrook, Wonewoe, Juneau Co., Wis.

One or two handsomely mounted red deer heads, attractive ornaments for any dining-room or hall, for microscope, telescope, sporting implements, camping outfit, scientific books, or offers. R. B. Hough, Lowville, Lewis Co., N. Y.

A new E-flat solo cornet, cost $22, for a self-inking printing press and outfit of same value and condition, also B-flat clarionet, books, papers, magazines, etc., for offers. C. W. Hughes, P. O. Box 96, Shreve, Ohio.

Hope's Manual of Sorento and Inlaid Work, cloth edition, price $1.25; would like to exchange for books on aquaria postage stamps, hammocks, or almost anything. G. Keppel, Zeeland, Ottawa Co., Mich.

A new one horse power horizontal steam engine, in complete running order, worth $60, for a first class coal stove, watch, or offers. Geo. L. Lamson, La Fargeville, Jeff. Co., N. Y.

A handsome Young America self-inking printing press, chase 3½ x 4¾ inch with 5 founts of type, 300 cards, and outfit complete, for a good wood-turning lathe, or offers. E. McLean, 443 Clermont Ave., Brooklyn.

Telescope, microscope, drawing instruments, and other things, in exchange for printing press and outfit, or offers; wanted, cards, type, etc. Ewing McLean, Greencastle, Ind.

I should like to exchange birds eggs with any one living in the far West, South, or in foreign countries. Wallace Ross, Lock Box 97, Rutland, Vermont.

I have some good specimens of Pentremites from the sub-carboniferous formation, that I would like to exchange for books, H. Russell, Grassy Cove, Cumberland Co., Tennessee.

Bonanza printing press, with three fonts of type, and assortment of blank cards; value of outfit $7.25; would like rifle, books, or offers, Geo. R. Simpson, Janesville, Bremer Co., Iowa.

Fine cabinet for sale or exchange; polished walnut and maple, 27 drawers, 3 closets, all locked; 7 ft. x 5 ft. x 19 inches; for any kind of specimens. W. W. Stockton, Box 190, West Chester, Chester Co., Pa.

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

INDUSTRIAL PUBLICATI

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, NOVEMBER, 1880. No. 11.

Collodio-Etching.

BY BENJAMIN HARTLEY.

WE may not be able to find anything altogether new in this age of progress, but we do see everywhere the revival and improvement of many old things. Ancient methods and materials are being rediscovered in every branch of science, art and mechanics.

In the midst of these revivals we find copper-plate etching taking quite a prominent place; and more than one magazine is devoting itself to the advancement of this old branch of art. Four hundred years ago etching was studied and used by the best painters, but during the last century and early part of the present one, this art, as distinct from engraving, was almost unkown. In fact it is only within the past twenty years that it has revived as an independent study.

At the present time we find, both in Europe and America, the *Etching Club* in place of the Sketching Club.

To *etch*, means to bite or eat, from the Dutch word *etsen;* so that those lines only that are eaten away or bitten out by acid from the plate are etched.

Many suppose that etching on copper is an easy matter, because the picture is drawn with a needle instead of being cut with a burin; while truly, as Mr. Hammerton says, it is exceedingly difficult. This difficulty arises from two causes; first, the etcher does not see his work properly as he proceeds; and second, mistakes or misfortunes in the biting, which are of frequent occurrence to the inexperienced, may destroy all the relations of tone. Besides, it is an expensive pleasure. Plates and press cost more than most of the readers of the YOUNG SCIENTIST would care to invest; so I wish to lay before them a process by which they can more easily, and with less expense, duplicate their sketches than by copper-plate work. It is not etching, properly so called, but simply drawing with

a needle on a prepared glass plate, which is afterwards printed like a photographic negative. It was suggested and tried more than ten years ago, but was laid aside for various reasons which I will not stop now to explain.

Those who have the first volume of the YOUNG SCIENTIST will find in its lessons on photography all the apparatus and materials named which are necessary for preparing the plate. It is done just as a photographer goes about making a negative. The glass is first thoroughly cleaned and flowed with collodion, then it is sensitized, or coated, in a bath of nitrate of silver. This can be done in a shallow porcelain or glass tray with a silvered wire hook to lower and raise the plate, as seen in Fig. 1.

Should the reader not care to prepare his own plates, he can get them from a photographer for from ten to twenty-five cents each.

Cabinet size I find the most convenient for small studies. This will make a picture 4 by 6 inches.

For the first attempts the plates should also be varnished with a good thin negative varnish, as the film is so delicate that the slightest touch will make an impression. The sketch has now to be transferred to the plate, and in order to have it, when printed, the same as the original, it must be reversed. If the drawing is just the right size, and made with a soft pencil, it can simply be turned over on the varnish, and the back of it rubbed lightly with the finger, (the varnish being dry)

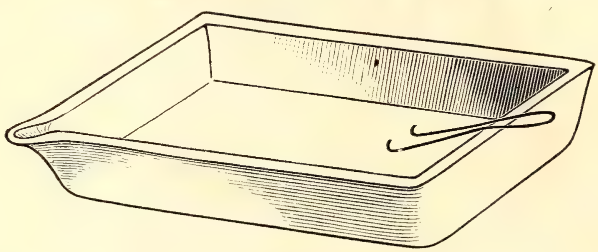

Fig. 1.

The only hint necessary about this part of the process is to be sure and lower the plate regularly, without stopping, into the solution. The advantage of the tray over the standing bath, is that you require but a small amount of silver solution to cover the plate. Sensitizing is done in a dark room.

Now, if you have a camera, you can point it at a perfectly white screen and expose the plate for about twenty seconds, and then flow over it a solution of protosulphate of iron. (See Vol. 1, page 118). The iron will make the film opaque, and of a grey color. Wash well and dry, and the plate is ready for the picture.

If you do not possess a camera, (it is not necessary) you can just open the door of your dark room, and let a strong white light fall directly upon the plate a couple of seconds, and then develop, with weak developer, as before stated.

when the outline will be seen on the plate as the paper is raised. This, however, can only be done on varnished plates, of course. Another method will be treated of hereafter.

The next thing of importance, is a stand something like a photographer's retouching frame. This is to rest the plate on while drawing with the needle, because by this process you can see the picture distinctly as it progresses. I will tell you how I made one. I took the frame of a broken slate and screwed strips of wood to the sides for legs, thus making it to stand like a square easel. Then I took two pieces of wood half an inch wide and a quarter of an inch thick, and just as long as the inside of the frame; to each piece I fastened a thin strip to the narrow side as long as the outside measurement of the the frame, and with screw eyes near the ends attached them to the frame

behind, thus letting the former pieces project in front for the plate; as seen in the accompanying illustration (Fig. 2.)

Placing a sheet of white paper on the table behind the frame, light will be reflected against the under side of the plate, and every dot and line will be distinctly seen as made.

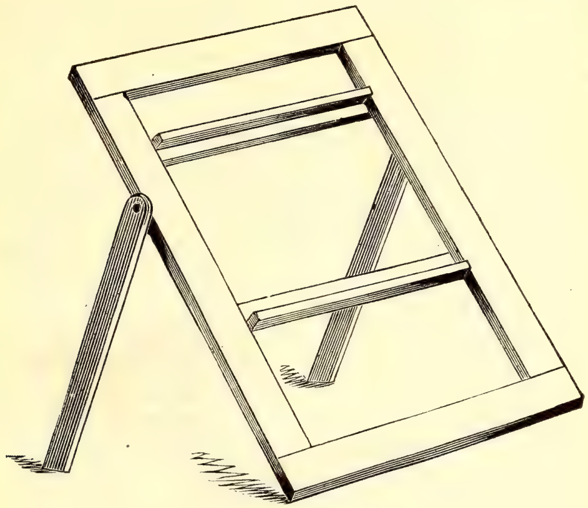

Fig. 2.

Another thing requisite is a good magnifying glass. I use two glasses arranged like a pair of spectacles, on a stand, and held by it in position over the plate.

We now come to the needles to be used in drawing. Take three needles of different sizes, fine, medium, and coarse, and tie them to pieces of wood like the handles of camel's hair brushes. Let the point of the needle project from the end of the stick only a quarter of an inch. This keeps the end firm. A darning needle being used for the largest size, you must file the point until it presents, under the magnifying glass, the long lozenge shape of a graver.

And now, if you have studied the drawing lessons given in the second volume of the Young Scientist, or have some independent knowledge of art, you will be able to go to work on the picture.

Put the plate on the frame. Take the finest needle and go over the entire outline. Let the subject be a simple one to begin with. Then, with fine lines, put in the shading of the distance; the middle distance, with the medium needle, may be a little bolder; while the foreground lines make broad and coarse. The plate, held up to the window, will be a transparency of your picture with light and shade reversed, and will show any defects. Other details I will have to leave for another paper.

Ornamental Turning.

(*Continued from page* 110.)

ONE thing we feel bound to advise, and that is, not to have a large case of tools, as made by some of the best makers, but a few well-assorted tools in long and short handles, according to their nature. This, of course, applies to hand-tools. Having practiced and made many things with such tools as are already possessed, it may be the desire to make an addition to the stock of apparatus. In this case an oval chuck will be the most useful, because we have facilities for a deal of eccentric work with the cutter. The oval chuck is a beautiful tool to work; its action being obtained by two steel pallets working round a ring—that is, fixed to the mandrel-head; in order to obtain the dif-

ferent degrees of ellipticity, this ring is moved from a given point. To work this chuck a slow motion must in all cases be used, in order to stay the vibration that is otherwise caused by the oscillation of the slide of the chuck. To determine the difference between the major and minor axis of the ellipse is a simple matter. For instance, if the ring is moved ¼ in. from the centre, the difference will be just ½ in. This gives an example, and it must be clearly seen the ellipse is exactly twice the size one way to what it is the other. Many beautiful patterns may be executed with this chuck, by dividing with the wheel that is on the front of it. In dividing with this instrument it must be obvious to all that the division must take place on the wheel, as the mandrel must necessarily revolve with the action of the chuck. A few practical lessons or hints on this tool will soon enable a complete novice to overcome its difficulties. When the use of this chuck, to a certain extent, is mastered, and another addition is required, we should recommend as the best an eccentric chuck, because the combination of the oval and eccentric produce some very beautiful work. The latter, when used with the former, should be fitted with a transfer chuck; it will then run true on its place. In continuing to give an account of the various additions to be made to an ornamental turning lathe, we do not wish our readers to labor under the impression that all the various things we name are absolute necessaries, but, from a long experience, we feel enabled to advise the best means of proceeding, if it be the wish to do so; though, before making any further purchases, be certain that you know the use of that which you already have. The dome chuck will be found the next most useful addition, as some very pretty work can be done with it, and to a very limited extent it takes the place of the spherical slide-rest. This chuck may be worked in conjunction with the oval and eccentric, and most curious results obtained. One of its principal uses will be to cut square or hexagon bases; with the slide-rest set to the surface, this kind of work may be done in various ways. Some prefer one, some another.

In proceeding with additions to the lathe, a drill-spindle, with a set of large moulding-drills, will be found a very useful thing to have; this also enables the turner to produce some very elaborate work with very little trouble. Passing again to chucks; the geometric chuck is one that to some turners gives a deal of satisfaction, and it certainly is a most beautiful tool; but, at the same time, it does little more than what the chuck does, leaving little scope for the the operator's powers of design. We prefer to see some of the beautiful tazzas, vases, etc., that are done by some of our readers, who excel in the use of the more simple chucks and cutters. When we come to all these expensive additions, naturally a large expenditure is necessary, but it is not at all necessary to spend a large sum to produce some fine work.

Science in Common-place Things.

IT is an old proverb that a man cannot raise himself by pulling on the straps of his boots. Something almost as wonderful can be done however: A man can easily raise himself by the pressure of his own breath, and if time were given him, it would not be impossible for a man to raise himself to the top of a house by this means. *How* it may be done we may explain in a future number, but in the meantime we will tell our readers how to perform an experiment almost as wonderful, and that is, to blow an egg out of one wine glass into another. Now an egg is a tolerably solid affair, weighing on the average about two ounces. If we were to attempt to blow it about, or support it in the current of air propelled from the mouth, we would probably fail, but if we proceed as follows, success is almost certain after a few trials.

Get an egg, and lest it should fall and make a mess, it is well to have it hard boiled. Then select two wine glasses in which the egg will nicely fit, (or if you have the glasses you may select the egg—either way will do), and place the two wine glasses as shown in the figure, but rather closer together, as it will be found difficult to send the egg as far as the dis-

tance there shown would indicate. A sharp puff of breath applied as shown in the engraving, will cause the egg to leap from one glass to the other.

The rationale of this striking experiment is very simple. An egg presents considerable surface, and the glass serves to concentrate and confine the force of the current of air to this surface. We have, therefore, a strong current passing down the very narrow space between the glass and the egg, and then exerting its force on a broad surface to raise the egg.

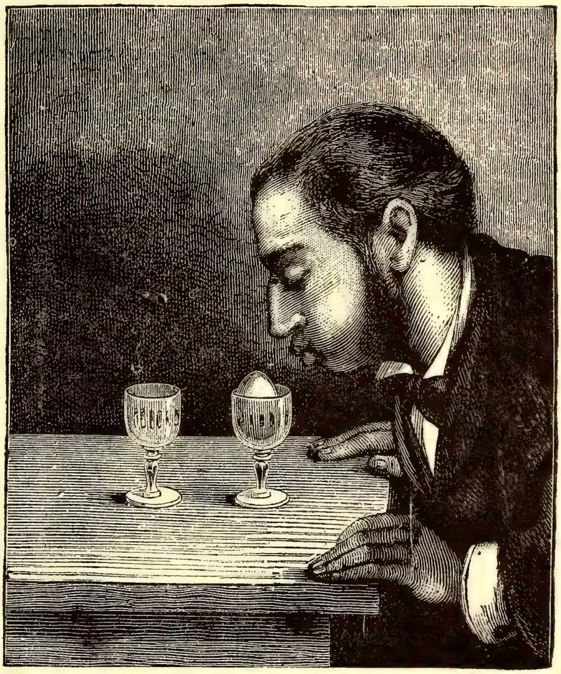
It is evident that we must send the current *between* the glass and the egg; it will not do to blow directly *on* the egg. The action is then something like that of the hydraulic press, and the experiment never fails after the operator has had a little practice. This was one of Faraday's favorite lecture experiments, and we ourselves have often performed it to the astonishment of large audiences.

Home-made Telescopes and Microscopes.—XI.

NEW FORMULA FOR A MICROSCOPE OBJECT-GLASS BY MR. WENHAM. (*Continued*).

At the commencement of the year 1873, the author caused a few object-glasses to be made, with a middle of the form of Fig. 18, the performance of which was very satisfactory. In this the extreme rays pass at more favorable incidences, and within the angle of total reflection. The upper lens is of dense flint.

When the experiments on the single front were concluded, and the remarkable corrective power of the triple back in conjunction therewith had been proved, the next attempt was to make the middle also a single lens, leaving the entire color correction to be performed by the one bi-concave flint in the back. After numerous trials it was found that though something like over-correction or negative aberration could be obtained with the back,



LIFTING AN EGG BY THE BREATH.

in the degree requisite for balancing the under-correction of the single middle and front when set at the prescribed distance of the aplanatic focus, yet by trial on the mercury globule all the results invariably displayed two separated color-rings; these could not be combined by alteration in the radius of the lenses. By projecting the blue or red, or visible rays of greatest and least refrangibility through the system, the cause became apparent. The left hand section of this object-glass is shown in Fig. 19. The rays from the focus are slightly divided by the first front surface. On emerging from the back the separation is increased; the red ray (*r*) is outwards, and the more refrangible or blue ray (*b*) inwards. Next the divergence of these two rays is extended by the middle single lens. The following crown lens extends the angle of divergence so far that the flint lens of the back triple cannot recombine them; and they emerge at two distinct zones, shown by the practical test of the "artificial star" or light-spot reflected from a mercury globule, viewed within and without the focus.

It might be supposed that these rays at their final emergence can be so refracted as to project the blue outwards. A cross-point would then occur at a fixed conjugate focus in the body of the microscope, at which all rays would be combined, and if this focus was adjusted to that of the eye-piece, achromatism and final correction would be the result. But to meet the various conditions occuring in the use of the microscope, the conjugate focus constantly alters in position, this being affected by every change of eye-piece, length of tube, or adjustment for thickness of cover; therefore a correction for a fixed point cannot be maintained. Achromatism in the microscope object-glass, like that of other perfectly corrected optical combinations, must be the re-union of the rays of the spectrum close to the final emergent surface of the system. The remedy suggested by these experiments appeared to be in a transposition, that is, in placing the over-corrected triple in the middle of the entire object-glass; this would at once cause a convergence of the blue and red rays. A single lens of longer focus at the back would then bring these rays parallel at the point of final emergence.

By projection in a diagram, this condition was apparently realized. The dispersive power of the flint (density 3·686) was taken by the refractive index 1·76 of line H in the blue ray of the spectrum, and 1·70 of the line B in the red ray. The refraction of the corresponding rays in the crown (density 2·44) was 1·53 H and 1·51 B. With these indices the rays are traced in Fig. 19. The radii in the right-hand half section are these of an "eighth" of the new form drawn about 15 times the size of the original. The single front is of the usual form, as this is much alike in all cases. The radius or focus of the single plano-convex back is about four and a half times that of the front, and the focus of the middle (triple) three times. The passage of the blue and red rays at the extreme of the pencil is shown in contrast with the preceding, the separation from the same front being alike.

The inner and outer, or blue and red rays, after passing the first surface of the triple middle, meet the concaves of the flint, which refract the blue rays to a greater extent than the red, and cause them to converge (instead of diverging, as in the opposing half diagram) so that at their exit from the triple they meet and would cross, effecting what is known as "over-correction;" but this is so balanced and readjusted by the single back of crown-glass that the rays are finally united, and emerge in a state of parallelism. This form of object-glass is suitable for the high powers, or such as have a cover adjustment, viz., from the "½-inch" upwards; perfect color-correction is equally to be obtained in all of them.

It may be asked by some who have devoted their attention to the higher branches of optical mathematics, why the above result should have been worked out entirely by diagrams. But it has been found such a difficult task to calculate the passage of the two rays of greatest and least refrangibility through a combination having sixteen surfaces of glass of three different densities and refractions,

that even first-class mathematicians have hitherto shrunk from the attempt.

Diagrams, however, are surprisingly accurate in their capability of indicating causes and results in the microscope and object-glass; for these lenses are minute, with deep curves and abrupt refractions; so that if the projection is worked out

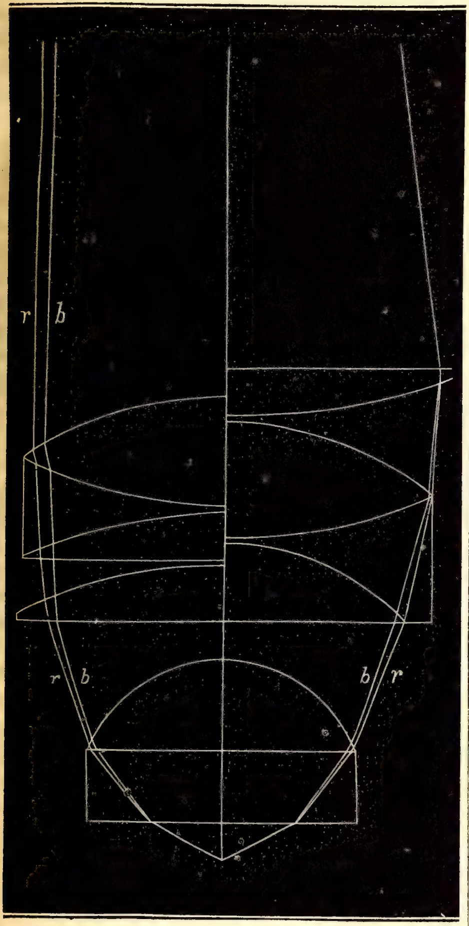


Fig. 19.

some fifty times the size of the original, small errors can be detected. The work should be commenced at the back from a long conjugate focus, which not being a constant distance, may be taken as very near to parallelism. The high powers all have the means of correction within this distance, and perform better with a long posterior focus than with a very short one. The relative indices for the two or more rays should be marked on a large pair of proportional compasses, the long limb representing the sine of the angle of incidence, and the short one that of refraction. Both the sines ought to be set off in a diagram behind, and neither of them in front of the ray in couse of projection; this leaves the way clear, with the least confusion of lines.

At the same time a second or counterpart diagram should be at hand, to which the rays only are transferred as soon as their direction is ascertained; with these precautions a mistake is scarcely possible.

Now it is hoped that some improvements may be effected by this investigation, on account of the simplicity attained in the combination, in which we have two single lenses of crown, whose foci bear a definite proportion to each other; while all the corrections are performed by one concave of dense flint, the acting condition of which is not altered by the influence of any other concaves acting in the combination, and hitherto taking a share of the duty. This one flint is now to be considered singly as the heart and centre of the system in reference to the correction of the rays entering and leaving.

This memoir is of necessity incomplete. for want of definite information concerning the optical properties of various kinds of glass. Nothing of importance has been published since Fraunhofer's Table containing the refractive indices for each of the seven primary color-lines of the spectrum for ten kinds of glass. Great advance has been effected since that date in the manufacture of optical glass, a most complete collection of which, of every variety, has been made by the Messrs. Ross, up to the present date. Selected specimens from this will be worked into prisms, and the relative spectra mapped out by the Fraunhofer lines, leading, it is hoped, to the discovery of a combination of crown and flint glass which shall be free from secondary spectrum or absolutely achromatic ("Proc. Royal Soc.," No. 141, 1873).

Three Amateur Workers—and What They Did—III.

BY FRED. T. HODGSON.

THE next day being Friday, Jessie and the boys had some little messages to perform for their mother. They were soon relieved, however, and immediately repaired to the shop, where they found their father waiting for them.

"Now, Pa," said Fred, "please show us how to complete the work-bench."

"Well," said Mr. Carpenter, "we must nail two of the cross pieces on to the legs, minding to keep them even with the tops. See, also, Fred, that the cross pieces are even at their ends with the sides or edges of the legs."

"Now then," said Mr. Carpenter, after Fred had nailed the cross pieces well on to the legs, "we must get two pieces of inch boards, twelve or fourteen inches wide, and twelve feet long, for side pieces." Fred and Ellwood soon found the pieces required. With the aid of their father they nailed these pieces on the legs, keeping the latter about one foot from the ends of the side pieces, and even with its top edge. They also took care to have the legs placed at right angles with the top edges of the side pieces.

Three cross pieces yet remained to be put in the bench between the two legs as now placed. This was an easy matter, as one was placed in the centre, and the other two midway between the legs and the centre one. These three cross pieces were kept in their places by being nailed fast to the side pieces. The bench was now ready for the top, which was formed of three pieces of plank, one and a half inches thick, and nearly thirteen inches wide, and twelve feet long. These were well nailed on, and the nail heads were driven deep into the wood by a small steel punch, called a "nail-set." This process of sinking the heads of the nails in the wood, is to keep them out of the way of the plane irons, chisels, gouges, and other edge tools that will be used on the bench. The bench now looked like a large table three feet two inches wide by twelve feet long. Mr. Carpenter cut the ends of the side pieces beveling, and bored about twenty holes in them, for a movable peg of wood, to be inserted when the edge of long stuff is to be operated on. A bench

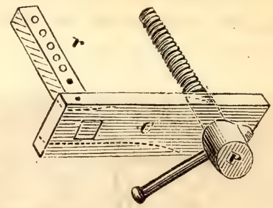

Fig. 6.

screw that Mr. Carpenter had provided, at a cost of seventy-five cents, was next produced and fitted in a jaw-piece, on the lower end of which was a slide-piece to keep the jaw parallel when in use.* The slide-piece was perforated with half-inch holes, in which a loose iron pin is intended to be put when in use, to hold the jaw parallel with the leg of the bench.

A round hole, large enough to allow the screw to pass through, was then made in the leg and side of the bench; a mortise was also put through the leg near its bottom end, great care being taken that the two holes were the proper distance apart, and that the round hole was bored at the proper distance, so that the top of the bench and top of jaw would correspond.

All being now ready, Mr. Carpenter put the jaw and screw in place, and Ellwood took the nut and held it on the inside of the bench leg, while his father inserted the screw and wound it up until the jaw was good and tight against the side of the bench. This brought the nut also tight against the inside of the leg and in proper place. It was fastened there with two long screws and a few nails.

---

*Fig. 6 shows how the screw and jaw were fitted together before being put in the bench, *P* is the screw, the arm of which goes loosely through the jaw, *C*. There is a groove turned in the neck of the screw, and a piece of hard wood with the end cut to lap round the neck in the groove, and of the exact thickness that the groove is wide, is driven through a mortise in the edge of the jaw, down in this groove. This holds the jaw and screw together, and, as the wooden nut is fastened on to the inside of the bench leg, it permits the jaw to move to and fro whenever the screw is turned in or out; *r* shows how the slide is fastened into the jaw, and the holes for the iron pin.

The work-bench* was now completed with the exception of a "stopper" in front, on the top. This was soon got over, however, for a mortise one and a half inches square was put through the top plank, just alongside of the front

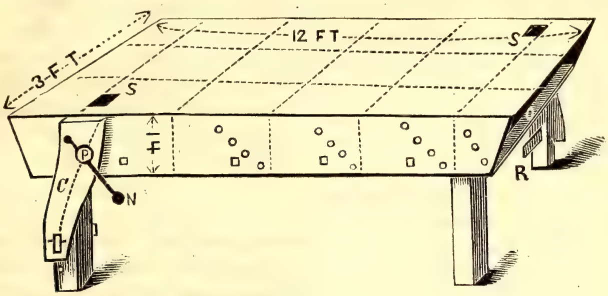

Fig. 7.

cross-piece, and a piece of dry hard wood, $1\frac{1}{2}$x$1\frac{1}{2}$ inches, and six inches long, was driven into the mortise, with the top end left above the surface just a little mite. It is so arranged that it can be driven down or up, at will. The opposite side of the bench was also furnished with a screw and "stopper," and holes were bored in the side so as to receive a peg, same as the side described. Mr. Carpenter thought it would be as well to finish both sides of the bench alike, so that the two boys, or himself and one boy, could work on it together.

The bench was now placed in position on the floor, and as there was a window opposite to each end, it was arranged so as to suit the light.

"Now, Ellwood," said Mr. Carpenter, "bring the planes from the house, and put them on the bench."

The planes were forthcoming at once, and consisted of a smoothing plane, a jack plane, a fore plane, and a jointer. The bodies of these planes were made of good dry beech wood, for Mr. Carpenter wisely thought it would be better to provide the boys with wooden than iron planes, as the former would stand more rough usage without becoming useless, than the iron ones.* He told the boys the

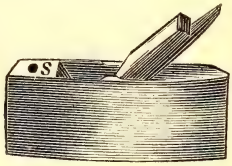

Fig. 8.

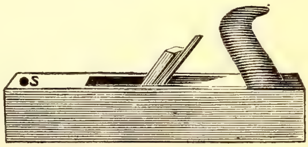

Fig. 9.

planes had better not be used until they had been well oiled all over with raw linseed oil, two or three times, and to

*Fig. 7 shows the work-bench when finished. *C* is the jaw; *P*, the screw; *N*, the lever by which the screw is operated; *R* shows the slide; *S* the stopper. The dotted lines running across the top of the bench and down the side, show the positions of cross pieces. The side pieces are well nailed on to these cross pieces. The dotted lines running lengthwise show the joints of the planking that form the top. This planking is well nailed on to the cross pieces. On each end of the bench a board is "cut" in between the side pieces and nailed; these form shelves, as shown at *O*, and are very convenient for planes, squares, or other tools. The bench should stand firm on the floor, and should be solid and "out of wind," or not twisted on the top.

*Fig. 8 shows the smoothing plane. It should be from 7 to 9 inches long, and have an iron from 2 to 2⅜ inches wide.

Fig. 9 is the jack plane. This should be from 16 to 18 inches long, and should have an iron from 2 to 2¼ inches wide.

Fig. 10 shows the fore plane, which is from 20 to 22 inches in length, with an iron from 2¼ to 2½ inches wide.

Fig. 11 shows the long jointer. This plane is made from 24 to 30 inches in length, and is only intended to be used for the most exact work. It requires more care than any of the bench planes, owing to its great length. To do good work, it requires to be perfectly straight and out of wind, and when not in use it should be put in a dry flat place, face downwards. *S* shows the "starter" on each plane. It is formed of metal or hard wood, and is let into the plane about half an inch.

have it well rubbed in on the ends. He explained to them that the oil would prevent the planes from checking, and render them less liable to be affected by dampness, and makes them somewhat heavier, which is an advantage to the two larger planes.

Mr. Carpenter also showed the boys how to draw the "irons" out of the planes by "tapping" the "starter" gently with a hammer or mallet; he also described the uses of the different planes, stating that the jack plane was used for taking off the rough surface of lumber, or cutting down irregularities. He showed them that the iron should be ground a little rounding, to enable it to work well on rough stuff. The fore plane, or "try-plane," as some workmen call it, he said, was for the purpose of making the surface even and fair after the jack plane had taken off the rough. "I will show you," he said, "how to use this and the other planes properly, when we get fairly to work, and in the meantime I will just say that the smoothing plane is used for smoothing off joints of frame-work when put together; for fitting work, squaring up end-wood, and smoothing work in general. It should be kept very sharp, and set very fine, and if in good order will make shavings like ribbons of silk. The jointer is used for jointing all kinds of stuff straight and square. It is indispensible in making glue joints, or doing any work where long straight edges are required.

(To be continued.)

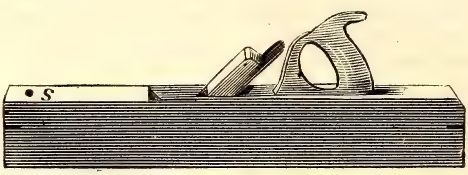

Fig. 10

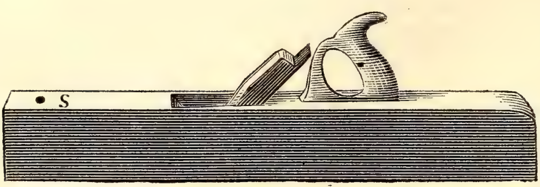

Fig. 11.

Water-Proofing with Paraffine.

SOME time ago, a method was devised for employing paraffine as a means of rendering leather water-proof, also the various textile and felted fabrics, and, subsequently, improvements have been made on this process, which consisted chiefly in combining the paraffine with various proportions of drying oil, it having been found that paraffine alone, especially when applied to fabrics, became to a considerable extent detached from the fibre of the cloth after a short time, owing to its great tendency to crystallize. The presence, however, of even a small quantity of drying oil causes the paraffine to adhere much more firmly to the texture of the cloth, sufficiently so, it is found, for all ordinary purposes, from the oil gradually becoming converted into a tenacious resin by absorption of oxygen.

In the application of this substance for water-proofing, it is first melted together with the requisite quantity of drying oil, and cast into blocks, and the composition can then be applied to fabrics by rubbing them over with a block of it either cold or

gently warmed, or the mixture may be melted and laid on with a brush, the complete impregnation being effected by subsequently passing it between hot rollers. When this mixture is applied to cloth such as that employed for tents, it renders it very repellant to water.

A very advantageous application of the paraffine mixture is made to various kinds of leather, one of the most convenient ways of accomplishing this being to coat the skins or manufactured articles—such as boots, shoes, harness, etc.—with the melted composition, and then to gently heat the articles until it is entirely absorbed. Thus impregnated, leather is not only rendered perfectly water-proof, but stronger and more durable.

How to Turn Boxes.

FIRST, then, as to the material to use; this is to a certain extent a matter of taste, but for the uninitiated to begin or practice upon, there is nothing like boxwood. It is both pleasant to work, and comparatively inexpensive; this, as a quantity is likely to be consumed, is an important matter. We will take a piece, say 3½ to 4 inches in diameter, about 4 inches long, and in order to rough it down, first, make the two centres, and indent one end to receive the prong-chuck, place it in the prong and bring to bear the poppit-centre, then take a cup chuck and fit the end of the wood into it about ½ inch deep, slightly taper and drive it in as lightly as possible. The most effective way of driving it in without damaging the face of the chuck is to simply place the wood in the chuck, hold it (the wood) in the hand and strike the end of the wood; this will cause it to become quite tight; if the face of the chuck is placed on the bench, it is likely to become bruised or marked, and so cause it to run out of truth, but a little experience will soon teach all these points better than all the writing. So far, then we have the wood chucked ready to begin operations. The first part to make is the lid, or top of the box. This must be carefully turned out the desired depth, and for a beginner, it will be less difficult to fit if made slightly taper, but it is better, when a little further advanced, to make the fitting perfectly cylindrical. When this is turned out, and the face of the inside finished, which must be done at the same time, to save the trouble of rechucking it, the top must be cut off with a parting tool, and then it can be fitted to the bottom; and when this is done, it forms a chuck for the purpose of turning it. This will save all further trouble, and the box may be finished, as it were, all in one. If it is to be ornamented, that must be done without removing the top. The inside of the bottom must not be taken out till the last thing. Now, it may happen that having finished a box of this description, and made a very good fit of the top and bottom, in fact, quite satisfactory in all ways, that upon a re-examination at another period, say the next morning, it will be found that it does not fit at all. This is caused by the wood shrinking, sometimes it will expand, and hold the lid so tight that it will be difficult to remove it. When this is the case, of course it is an easy matter to make it easy. Not so however, when it is already too easy, but these are difficulties that all turners have to contend with. The best way to get over this difficulty is to screw the top and bottom together, instead of making them plain-fitting. This is a more difficult process, and will require a deal of practice, especially if the turner has not a traversing mandrel to his lathe; it is at the same time to be overcome with practice, first having had some practical information on that particular point. Now it will not do for a novice, when he has made a very fair job of his first box in wood, to go directly to ivory, for it is an expensive material; moreover, the second attempt may not prove so successful as the first, and if this is the case a great disappointment and loss may occur.—*Forge and Lathe.*

Corn Starch Paste.—Corn starch makes a good paste for scrap-books. Dissolve a small quantity in cold water, then cook it thoroughly. Be careful and not get it too thick. When cold it should be thin enough to apply with a brush. It is not so liable to mold and stain the paper as paste made from other kinds of starch.

To See Objects Apparently through the Hand.

THE following curious experiment throws a good deal of light upon the facts connected with vision.

Take a sheet of ordinary letter paper, roll it into a tube, and through it look at some distant object with the left eye, the right eye being also open. If the hand be now held before the right eye, so as to cut off the view of the object by that eye, the object will still remain visible to the left eye. Strange to say, however, it will *appear* to be visible to *both* eyes, and a hole, the exact size and shape of the tube, will appear through the hand as shown

LOOKING THROUGH A HOLE IN THE HAND.

by dotted lines in the engraving! In other words, it will appear to us as if there was actually a hole through the hand, the objects being seen through that hole.

This singular optical illusion is evidently due to the sympathy which exists between the two eyes from our habit of blending the images formed in both eyes, so as to form a single image. The result is startlingly realistic, and forms one of the simplest and most interesting experiments that we know of.

Editorial Notes.

Mr. Wenham's Paper on Object-Glasses.

THOSE who read these papers will see at once that *some* of them are intended for any but "young" scientists. Indeed, it will require a very intelligent student to follow the one in the present issue, and we would have omitted this, as unsuited to our columns, if it had not been that to do so would have left the series incomplete. We have thought it best to give Mr. Wenham's papers entire; a large portion of them are so plainly written that any intelligent boy can understand them, and the rest is of value to such a number of our subscribers that the space can not be considered wasted.

BOOK NOTICES.

The Students' Illustrated Guide to Practical Draughting. A Series of Practical Instructions for Machinists, Mechanics, Apprentices, and Students at Engineering Establishments and Technical Institutes. By T. P. Pemberton, Draughtsman and Mechanical Engineer. Illustrated with Numerous Engravings. Price $1.00. New York: Industrial Publication Co.

This is a simple and thorough book by a draughtsman of twenty-five years experience. It is intended for beginners and self-taught students, as well as for those who pursue the study under the direction of a teacher, and having been written by one who has had a large experience in teaching, the wants of both classes have been very fully met. So far as regards the mere art of drawing, the advanced student will probably find little in this book that will assist him, but the chapters relating to gearing and screws, aim to give thorough and practical knowledge, not only as to the best methods of delineating them, but as to the true principles involved in their construction. In these departments the author has been assisted by the well-known mechanicians, Joshua Rose and John Walker, whose names are a sufficient guarantee of the excellence of the methods explained.

Levers of Archimedes, with the Fulcrum Found. By Will Powers. Philadelphia: G. W. Townsend.

These "levers" consist of a certain system of examining and studying any subject that may be proposed. The points to which special attention is to be directed are the cause, the essentials, the associations, etc., of the subject to be studied, and the so-called "levers" are printed blanks in which this scheme is fully laid out.

The idea is a good one; whether the "levers" will enable the student to carry it out or not is

another thing. One thing is certain, however, that the mere effort to do so must have a good effect.

Correspondence.

A Foot-Power Scroll Saw and How to Make It.

[The following letter will prove interesting, not only from the clear and excellent way in which our young subscribers are told how to make a cheap but very good scroll saw, but as showing the influence of our journal in teaching boys to work out these things for themselves. H. has succeeded admirably, and we hope that others who have good things that they have worked out themselves will send them to us.—Ed. Young Scientist.]

Some articles about scroll-saws have already been given in the Young Scientist. Perhaps another one would not be amiss, especially as it treats of a foot-power saw. This saw is thoroughly original, and leaves much room for improvements; therefore, any boy trying to make it will surely make some improvements to suit himself.

Take two strips of ash or other elastic wood, about 18¾ inches long, and ¾ inch wide. These strips are to act like springs; they also form the arms of the saw. The upper spring must be the strongest, and ¾ inch thick at one end, diminishing gradually to ¼ inch. The lower spring varies from ¼ to ⅛ inch. At the thinnest end of each spring, glue a small square of the same wood, and place the grain crosswise to that of the spring. This is to insure solidity, because a hole must be bored through the spring and small square to put the clamp in, as shown in Fig. 1.

Now find a nice smooth piece of board, not less than ½ inch thick, 8¾ inches wide, 38 inches long. This is to form the table of the saw. Make one end of the board round. Take two pieces of strong wood 1 inch thick, 1½ inches wide, and

Fig. 1.

4½ inches long. At each end of these, cut out a piece in which you insert the arms of the saw. Try to have as perfect a fit as possible, and make the upper arm slope a little downwards. This done, take your board, and, eight inches from the square end, cut a hole in which you tightly fit your two uprights, leaving them 1¼ inches apart, and 3½ inches from top of table, as shown in Fig. 2.

You can now take the arms of your saw and screw the thick ends firmly into these uprights. The thicker arm is for the top. Bore a hole in the board, on a straight line with the clamps, to allow the saw to pass through. The board, with the mounted saw-frame, can be screwed on a common table. You must screw the square end on the table, leaving the rest of the board outside.

On the lower arm of the saw adjust a brass strip, ⅜ of an inch wide, and make the two ends meet underneath. You now bore a hole through the two ends, through which a piece of stout wire is inserted. Your wire connects to a treadle. Leave the wire short enough to allow full play to the treadle. It is well to make one end of the treadle stationary.

Boys, your saw is finished. If you could mount it upon a real table instead of a board, you would have a much stronger hold and more power. I have done very fair work with mine. If any of you succeed and make improvements, write to the editor of the Young Scientist, and ask him to insert them in the paper. I have made a blow-pipe, which is half a putty-blower, run through an upright stick, and screwed on the end of the board in front of the work. H.

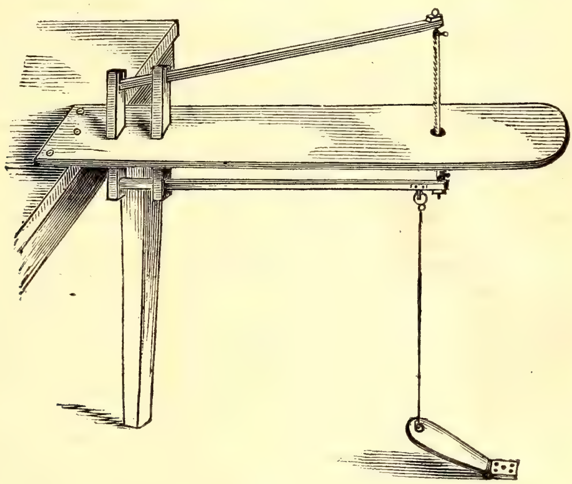

Fig 2.

Astronomy for Amateurs.

BY BERLIN H. WRIGHT.

THE PLANETS—DECEMBER, 1880.

(Calculated for the Latitude of New York City.)

	D.	H.	M.	
Mercury rises	13	5	33	morning
" "	16	5	41	"
" "	19	5	51	"

This will be a favorable time to look for this planet. On the 16th he rises 2h. 37m. before the Sun, and exactly at the time of beginning of the morning twilight. He should be looked for at the time of rising 26° south of the east point, and 5½° (a little more than the distance between the "Pointers") north of the Sun-rise point. He is in the constellation Scorpio, and about the time of sunrise may be confounded with the bright red star Antares, and though they will appear much the same in color, Mercury is the brighter, while Antares is nearly 7° further *north*, and does not rise until 6h. 20m. morn.

	D.	H.	M.	
Venus sets	10	7	10	evening
" "	20	7	34	"
" "	30	7	58	"

Venus is a beautiful evening star, and will increase in brilliancy during the remainder of '80, and until March 27, '81.

	D.	H.	M.	
Mars rises	10	6	10	morning
" "	20	6	7	"
" "	30	6	2	"

This planet may be mistaken for Mercury, which rises but a few minutes earlier. A comparison of their respective places on the 16th shows that Mars is 17m. 4¼° east, and 2½° south of Mercury, and inferior to him in brilliancy.

	D.	H.	M.	
Jupiter in meridian	10	7	17	evening
" "	20	6	40	"
" "	30	6	3	"

SATELLITES OF JUPITER.

The following are some of the principal and most interesting events which transpire in the Jovian system in the evenings of December.

ECLIPSES, NEAR APPROACH OF PLANETS TO THE MOON, AND OTHER IMPORTANT PHENOMENA, DECEMBER, 1880.

Dec. 1. Partial Eclipse of the Sun, visible only in the Antartic Ocean.
" 2. Moon Perigee ; tide highest.
" 2. Moon lowest.
" 4. Jupiter stationary.
" 4. Venus 4° south of Moon.
" 5. Uranus 90° west of Sun (*quadrature*).
" 5. Venus 19° in Sagittarius.
" 10. Jupiter 6° South of Moon.
" 11. Saturn 8° South of Moon.
" 12. Neptune 6° South of Moon.
" 12. Mars 6° in Scorpio.
" 13. Mercury greatest elongation west, 21° 8′
" 15. Moon highest.
" 13—16. Mercury brightest, and visible as morning star.
" 16. Moon Totally Eclipsed; invisible in North America, except on the Pacific Coast, where the Moon sets at sunrise totally Eclipsed. Eclipse begins in San Francisco at 5h. 35m. morning; Portland, Or., 5h. 36m. morn.; Sacramento, 5h. 40m. morn.; and at Salem, Or., 5h. 44m. morn.

Dec. 17. Moon Apogee; tide lowest.
" 18. Uranus stationary.
" 19. Jupiter 9° in Pisces.
" 21. Sun enters Capricornus; winter begins.
" 23. Uranus 6° North of Moon.
" 23. Mars very close to Mercury; 1° south.
" 24. Saturn stationary.
" 26. Saturn 2° in Pisces.
" 29. Moon lowest.
" 29. Mars ½° North of Moon.
" 30. Mercury 12′ North of Moon.
" 31. A Partial Eclipse of the Sun. In the eastern part of the U. S. the sun will rise more or less Eclipsed. At New York City the middle of the Eclipse occurs at sunrise, and the end at 8h. 44m. morning.
" 31. Moon Perigee; tide highest.
" 31. Uranus 13° in Leo.

THE MOON, V.—2d OR N.E. QUADRANT CONTINUED.

Between 110 and 112 are 61 minute craters, easily seen when the Sun is rising on the east side of the wall of Copernicus (112). The diameter of these craters has been variously estimated at from 400 to 700 feet. These craters are arranged mainly in rows, and so very close that but for the partitions they would form canals, which fact has lent strength to the belief that the so-called canals were originally continuous lines of craters. Above, and a little to the right, is Archimedes (120), a very large and regular walled plain 60 miles in diameter, with a wall averaging 4,200 feet above the interior, upon which are several high towers; the highest 7,400 feet. One astronomer has detected a minute crater within; a magnificent object against the rising or setting Sun. 129, and its companion to the right, are twin craters; depth of the companion estimated at 13,600 feet. Pico (131) is called an "insulated pyramid," and rises from a narrow base to the lofty height of 9,600 feet, and must form a fine sight from the surrounding plain. Plato (132) is another walled plain 60 miles in diameter, with three towers about 7,000 feet high. Some supposed craters have been observed within, but the peculiar feature of this object is the local shading of the interior. There is an alternation of light and dark bands within, which are believed to be variable. Sinus Iridum (P) is a beautiful object, almost as level as water, dark, semicircular, and surrounded by abrupt and high cliffs. The two promontories which reach out on either side are 140 miles apart, and very high and abrupt; best seen two or three days after First Quarter. Aristachus (148) is considered the brightest crater in the Moon, and is quite beautiful, even in a small telescope. The steep central hill shows with fine effect four or five days after First Quarter. The ring is 28 miles across, and in the west rises 7,500 feet above its inner, and 2,600 above its outer base. On the east the ring becomes a plateau, connecting it with the steeper crater Heroditus (149), north of which is a curious serpentine valley, nowhere exceeding 2½ miles in width, not unlike a dry river-bed. Owing to the great reflective power of this object, Herschel the I. mistook it for a volcano in eruption. It may be seen with the naked eye when on the bright side, and with a telescope when on the dark side. Above, and a little to the right are several mountains, the highest 6,300 feet. Pythagoras (176) is the deepest walled plain in this quadrant, measuring some 17,000 feet on the S.E. side.

These are the abbreviated descriptions of the most remarkable objects in the 2d or N.E. Quadrant, still leaving the whole southern lunar hemisphere untouched.

Penn Yan, N. Y.

Welding Cast Steel Cold.—A writer in the *Blacksmith and Wheelwright* says: "Cast steel can be welded cold by simple hydraulic pressure. Incredible as it may seem, it has often been done." We know that lead and the softer metals can be welded by great pressure but we were not aware that pieces of steel or iron could be so united.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

Wanted back numbers of "American Naturalist" and "American Journal of Science and Arts" (Silliman's Journal), for beautiful specimens, named, of American ferns, mounted or unmounted. Box 16, Pine Plains, N. Y.

Wanted, to correspond with some one living near the ocean beach; also some one living near any lead or copper mines. Ewing McLean, Greencastle, Ind.

Beautiful Beryls, Garnets, Tourmalines, Rose Quartz, Muscovite, Granites in variety, etc., to exchange for coins, shells, fossils, minerals, books, magazines—anything. Describe offers fully. C. Le R. Wheeler, Wilmot, Merrimack Co., N. H.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

Wanted, specimens metallic ores; will give in exchange fossil shells, Vicksburg epoch, Tertiary period; state kinds of ore. Philip Crutcher, Warren Co., Vicksburg, Miss.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing. P. O. Box 178, Wattsburg, Erie Co., Pa.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

I have some stamps which I will trade against other stamps, or offers; please send list of stamps you have to exchange. J., 226 West 22d St., New York.

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

Wanted, a household microscope, telescope, large lenses, well-mounted slides for the microscope, books on the microscope or entomology, in exchange for stuffed birds or minerals; describe offers, and state what is wanted in exchange. E. O. Tuttle, Hampden, Mass.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J.

Minerals to exchange for other minerals; state what specimens you have for exchange. Samuel Wynne, Box 54, Phoenixville, Pa.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa,

I have a four-legged and four-winged one-headed chicken, in alcohol, which I should like to exchange for a good breech-loading shot gun, or for standard scientific books. A. H., Box 500, Albion, Ohio.

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Wanted, scientific books, minerals, fossils, and Indian relics, in exchange for minerals, fossils, coins, old Continental and Federal money over one hundred years old (very rare), foreign stamps, A. W. Baily, Box 712, Atlantic City, N. J.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Idaho Mineral Specimens, for bound books on science, travels, history, biography, political, masonic, and others that are instructive. J. P. Clough, Junction, Lemhi Co., Idaho.

I have minerals (including fossils and dentrites), to exchange for minerals; also a papyrograph outfit, without press (worth $25), for offers. W. H. Eastman, Hyde Park, Mass.

Klose's celebrated "School for the Clarionet," new, $3; will enchange for telescope, microscope, piccolo. books, or offers. Rush Holbrook, Wonewoe, Juneau Co., Wis.

One or two handsomely mounted red deer heads, attractive ornaments for any dining-room or hall, for microscope, telescope, sporting implements, camping outfit, scientific books, or offers. R. B. Hough, Lowville, Lewis Co., N. Y.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. III. NEW YORK, DECEMBER, 1880. NO. 12.

Ivory Pagoda.

PERMIT me to answer through the columns of your valuable journal, a query that appeared in the last number, relative to the production of an ivory pagoda. For I have made one of these somewhat elaborate ornaments, which has been much admired, I need not say, much to my satisfaction.

First, then, the base to begin with. This was made of African blackwood, and to procure a piece of sufficient diameter was some considerable trouble, but I did, after all, and the diameter represents 6½ inches. This I screwed on to the largest worm or screw-chuck I have, which has a good large flange to it, consequently giving a good surface for the wood to bear against. Having well chucked it, I may say to turn it clean all over was the next operation. This done I set the drill-spindle with a drill I had especially made to make a half-inch hole, these being for the base of the pillars, eight in number, to fit into. Now to make the pillars, no difficult matter some readers may say, as far as one is concerned, but I found to make the eight all alike a difficult task, but by perseverance, and a little advice from one I will not mention, I arrived at a good plan, viz., I first cut off the eight pieces all one length, and made a corresponding number of small boxwood chucks all exactly the same length or distance from the nose of the mandrel, then turned the pillars to fit the holes already made in the base, and then fitted each one into one of the said chucks. I then set the slide rest to the desired taper, and made a note of what angle it was in case of its shifting by any means, and with the fluting-stops adjusted to the length began to turn them up. One being done, nothing remained but to take it off, chuck and all, and replace it by another, the stop screws of the top slide saving all necessity for the use of callipers, and when they were all done, much to my satisfaction, I

found they were all exactly alike in shape and size, and to flute them the same process was again gone through. Having gone so far, the next part was to place on the top of these pillars, a second piece of blackwood. This I did by screwing it on the smaller worm chuck, and drilling eight smaller holes than those in the bottom, to receive the top of the pillars, of course using the same division, with the drill set exactly to the same distance from the centre as when drilling the lower holes, and upon placing the top on its place, found all came square and upright; but upon proceeding I unfortunately found that I had made my slab too thin, forgetting that I wanted the bottom of the next tier of pillars to fit in the same hole. Here, as in many cases, the fact of an error often results in something more effective than the original idea would have been; in my case it certainly was so. Finding I had no room for what I wanted, I was of necessity compelled to place the second row of pillars between those at the bottom, and cover the holes already made with small ivory buttons with an eccentric pattern cut on them. This turned out very effective. Now the second series of pillars I desired to cut with a pattern of the same description your correspondent desires. Now this pattern is called the geometric staircase, and does to an extent represent a number of discs placed one on the other. To produce this, I used the eccentric chuck, and I give the setting as nearly as possible. The diameter of pillar one-half inch, the eccentricity of chuck throughout one-tenth. Use a small square chisel-tool in the slide-rest one-twentieth wide. The milled head of slide-rest must of course be set at zero, and this will necessitate moving it just one-half round, to shift the tool exactly its width. Having done the first cut, the dividing wheel of the eccentric chuck must be turned round one division of 96, and by proceeding in this way, the result will be what I say, a series of discs one on the other, and in a spiral form.

One little difficulty I found from the length of the pillars, which had to be supported by the poppit head, and when the wheel is shifted, a different centre is required for each cut. In order to obtain this, a flat end must be left, and before shifting the wheel for each alternate cut, the centre must be withdrawn and then replaced. It is rather a tedious job, and I for one was very glad when I had finished them; but the result amply repaid me for the trouble.—*H. Melvill in Forge and Lathe.*

Three Amateur Workers—and What They Did—IV.

BY FRED. T. HODGSON.

HAVING described the planes and their uses this far, Mr. Carpenter proceeded to explain to the boys how these tools were to be kept in order. He struck the "starter" on the jack-plane, which

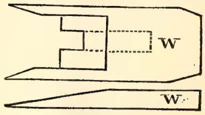

Fig. 12.

loosened the wedge and iron; he then slackened the screw in the rim and took it apart. The cutting part being new, as a matter of course it wanted sharpening,

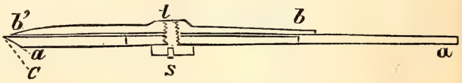

Fig. 13.

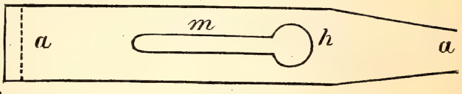

Fig. 14.

and as he had purchased an oil-stone along with the other tools, he produced it, and began to show the boys how to use it. Ellwood fairly screamed with delight when he saw the oil-stone, which was a

Fig. 12. w w, shows the wedge for adjusting and holding the iron, in two views.

Fig. 13 shows the "double iron" ready to put in the plane. The lower iron, *a a*, is the cutter, and the upper one, *b b*, is the cap. This cap serves a double purpose; first, to give the shavings the proper direction, and second, when placed close to the cutting edge, it prevents the cutter from tearing up cross-grained stuff. The two irons are

fine white Washita stone, nicely fitted in a walnut-wood box, which parted in the centre when opened for use. "Oh," said Ellwood, "that will be bully to sharpen

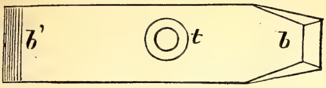

Fig. 15.

my jack knife on." "All right," said his father; "you may sharpen your knife on the stone, but you must be very careful and only use the ends of the stone, for if you rub your knife in the centre it will soon wear away, and become hollow, and then plane irons or other edge tools cannot be sharpened on it with any degree of satisfaction."

Mr. Carpenter warned the boys against using inferior oil on the stone. "If possible," he said, "always use pure sperm oil; lard or olive oil answers very well, but when used the stone should be fre-

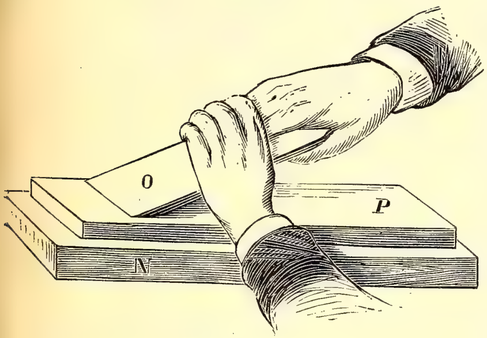

Fig. 16.

quently cleaned off, or it will get hard and full of dirt. Kerosene is excellent for cleaning an oil stone, and may be used occasionally for sharpening with. If at any time you want to sharpen a chisel or a plane iron, or other tool, and have no oil to use on the stone, you may use a little castile soap and warm water. This merely answers a purpose, and should not be resorted to oftener than can be helped.

"When sharpening a plane-iron, you should grasp it in the right hand, and place the fingers on the surface and the thumb underneath. The fingers of the left hand should be lapped over those of the right, and the thumb should be placed underneath to support the iron, which should be held at a constant angle of about thirty-five degrees, and kept square across the face of the stone. If, as may sometime happen, you have an iron that is wider than the stone, you must work it from side to side, so as to make the corners uniform with the middle. When the edge of an iron is required to be a little rounding, as is sometimes wanted in a jack-plane, a light roll must be given to the blade edgewise. You must not press too heavily on the iron while sharpening, as the edge will be liable to bend over, and become what is called 'wire edge.' When you think your iron is sharp enough you must turn the flat side down, keeping it *quite flat* on the stone, and gently rub a few times to remove the wire edge, if any has formed.

"If you hold the iron too upright, the edge will be too quickly produced, and will wear off much sooner than if the iron had been held, during the sharpening process, at a lower angle. You can easily see that if an iron is sharpened at an angle of forty-five degrees, which is the pitch at which it is fixed in the plane, the chamfer formed by the oil-stone would rest on the work, and would, consequently, prevent the edge from cutting. On the other hand, if the angle be too acute, the edge will be too thin to be durable; therefore, the angle of thirty-five degrees is probably the best angle for planes, chisels, and similar tools.

"It is always well to take the corners off the iron, for if they are left on they will be apt to leave marks on the work, and this will not be very nice."

Fred, under his father's immediate supervision, tried his hand at sharpening up the plane irons, and considering that this

---

held together by the screw, s, which is "tapped" into the boss, *t*, formed on the cap-iron, which is shown separately in Fig. 15.

The cutting iron is shown disconnected from the cap-iron in Fig. 14. The long slot, *m*, admits of the iron being adjusted longitudinally, and also, to a slight extent, sideways. The round hole, *h*, is a little larger than the head of the screw *s*, which permits of the irons to be taken apart without taking the screw, *s*, out entirely.

Fig 16 shows the method of holding the plane-iron during the process of sharpening. O is the iron, P the stone, and N the box in which the stone is cased.

was his first attempt, he made a pretty good job; it took him some time, however, before he could get rid of the rocking motion that all young persons seem to have in their hands when they first try to sharpen up a plane iron.

Mr. Carpenter was very particular in his instructions regarding the method of sharpening tools; and this was right; for it is very important that every young workman should know how to put and keep his tools in good order. And besides knowing how to put and keep them in order, it is equally essential that they *should* be kept in order, for it is impossible to do satisfactory work with dull tools, or tools that are in bad shape, or not properly sharpened. It is an old saying, that "A bad workman quarrels with his tools." The real trouble, however, is, that a bad workman does not know how to put his tools in order; if he could have managed his tools all right he would not have been a bad workman. As a rule, it requires more skill to care for and properly manipulate tools, than to do the work; hence, it will be seen that Mr. Carpenter was perfectly right in impressing on his boys' minds the necessity of taking great care of their tools.

A few evenings after this, Mr. Carpenter and his three children were again in their workshop, where everything had been made nice and clean by Jessie, the day previous.

"Now then, Fred," said Mr. Carpenter, "I will show you how to use the planes and saws, and after you have acquired the 'knack' of properly handling them, you may teach your brother Ellwood.

"In the first place, we will take a piece of inch stuff—all boards, planks, and scantlings are called 'stuff' by workmen, and, for the sake of brevity and convenience, we will adopt their modes of expression—three or four feet long, and from six to ten inches wide. It is rough, just as it came from the saw mill; we will lay it on the workbench, placing one end against the stopper. Now take the jack plane, see that the iron projects just a little beyond the face of the plane; grasp the handle in the right hand, place the left hand on the front of the plane, keeping the thumb towards you; now then, push the plane forward, pressing it down on the work during the cut; this you can do with very little exertion, if you slightly incline the body so as to cause its weight to rest partly upon the plane. On the return stroke the pressure must be discontinued to avoid friction on the edge of the iron. Indeed, it is sometimes better to lift the heel of the plane up altogether, on the return stroke, as by this action the iron will remain sharp a greater length of time, particularly is it so when the surface of the stuff is full of sand or grit."

Fred made a very creditable attempt—for the first one—with the jack plane, and the way he made the shavings fly, filled Ellwood and Jessie with delight. To make a shaving two feet long, seemed, in Jessie's eyes, something wonderful.

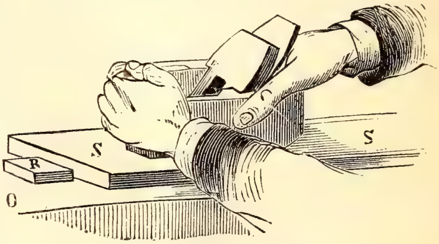

Fig. 17.

Fred planed off the board to the satisfaction of his father, and seemed quite pleased to think he had accomplished so much.

"But, Pa," said Fred, "What is it makes all these marks on the board where I have planed it?"

"Ah!" said his father, "There will always be marks left on a surface after a coarsely set jack plane. We must now have the board smoothed off with the smoothing plane, which, you will see, will make a nice smooth surface."

Fred then took the small plane, and, after receiving some instructions from his father, fell to and smoothed off the surface very nicely, much to the delight of his brother and sister.

(To be continued.)

Fig. 17 shows how Mr. Carpenter taught Fred to hold the smoothing plane when using it to smooth up stuff. R shows the stopper in the bench, O the work-bench, and S S the stuff being smoothed.

Apparatus for Preparing Caterpillars for a Biological Collection.

THE most common method for inflating and drying caterpillars, is that the caterpillar, after emptying its body of intestines, etc., by gentle pressure from the head toward the anus, be blown up with a straw inserted into the latter, and then be dried over the flame of an alcohol lamp.

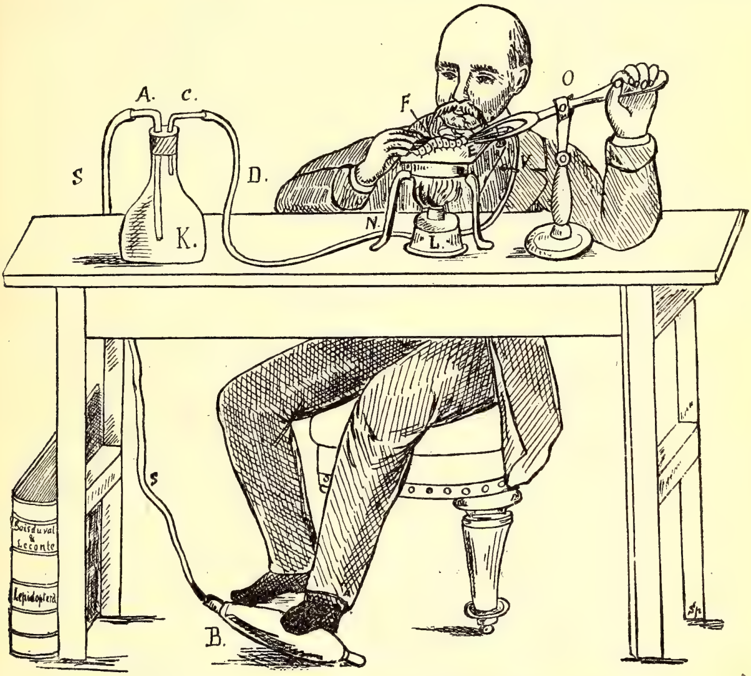

Fig. 1.—APPARATUS FOR PREPARING CATERPILLARS.

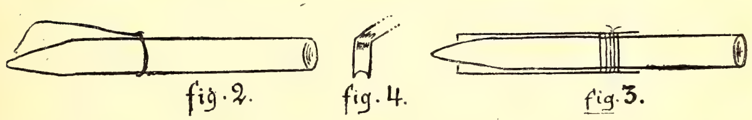


This method has two faults, first, that only one hand can be employed to give the body the required shape, and the other, that it becomes somewhat disfigured at its end by the inserted straw.

The Brooklyn Entomological Society has a collection of prepared caterpillars of butterflies, each specimen pasted on a piece of card-board with shellac solution, the card itself being held in a horrizontal position by an inserted entomological pin. The specimens show their natural forms as well as colors beautifully, and have been prepared by some members of the Society in the following improved manner. The bottle K, is tightly closed by a cork or rubber. Two glass-tubes, bent at right angles as shown, pass through the cork, the one A having a larger diameter, is connected by the rubber tube S, with the rubber bellows B, the smaller one C connects by the rubber tube D with a finely pointed glass tube E, on which the caterpillar-skin F is secured. The glass tube is held by the stand O, which allows vertical and horizontal movements, thereby facilitating the approach of the caterpillar to the heated metal plate that rests upon the tripod N, under which is placed the gas or alcohol lamp L.

The bellows is worked by the foot, and the air passing through the rubber tube S, and the glass pipe A, is compressed in the bottle by reason of the smaller diameter of the exit pipe C, causing a continuous and uniform current of air, which can be still further controlled by opening or closing the cock V. If it is desired to introduce warm air into the caterpillar-skin, the bottle K may be placed upon a sand bath. The size and fineness of the point of the glass pipe E upon which the skin is secured, depends upon the size of the caterpillar, therefore sevral sizes of them should be at hand.

To fasten the skin upon the glass-point, wind a common insect-pin around the glass, bend it along the pipe and make a small hook of the pin point, (See Fig. 2) or bind with thread two springs to the pipe, as shown in Fig. 3, having them bent rectangularly at the end, and the tips fitted to the pipe, Fig. 4.

Collodio Etching—II.

BY BENJAMIN HARTLEY.

BEFORE taking up the several details of the picture, I must go back a step to say a few words more about the plate. In the last number, I said that the plate had better be varnished when beginning to practice. Supposing, now, that you had made the attempt, you have discovered that the varnish is rather hard to scratch, and that is just why I told you to use it. When you draw on the collodion film without it's being varnished, you have to be exceedingly careful, as the film is very tender and delicate. Now I imagine you sitting with your unvarnished plate, and I know your first question must be, "How shall I get my sketch transferred to it?" Of course you cannot do as before intimated, that is, turn it over and rub it on the back, for by so doing you would ruin your plate. You must draw it directly on the film. This is somewhat difficult with a pencil, because, no matter how soft it is, it will now and then catch on some particle of grit, and make a line through the film when you only desire a tracing on the top, to be filled up afterwards by very different lines with the needle. You require first simply to "block in" your subject, and for doing this you will find a very small, sharp-pointed stump or blender to be the most useful tool. Those made of wash leather are to be preferred to the paper ones, *provided* they have good points. With one of these stumps you can indicate the outline, and, if used gently, the false strokes will not injure the drawing. When your picture is thus sketched, you take your finest needle and proceed with the distance as before stated.

The reversing of the picture is another point I promised to explain. If the picture to be copied is *not* just the right size for your plate, you must make an outline sketch of it, the proper dimensions. Then, placing a piece of transfer paper on your table or drawing board, put on it a piece of drawing paper, and on the top lay your sketch and go over the lines with a pencil or ivory point. When this is done you will find on lifting the paper an exact reversal of your subject which you can easily copy on the plate.

Now we will take up the details of the picture. I can only give a few general hints, but hope they will be sufficient to guide the amateur in his studies. First then, take the water. If it is still, as in a pond, or smoothly flowing, as in a deep river, the lines must be kept very straight, both horizontally and perpendicularly, in order to give the effect of transparency and flatness. Let the lines be few, except in the reflections. To represent the current of a stream, lines are used which are sometimes curved, but more frequently straight, although not horizontal, as they all run towards some perspective distance or vanishing point. In broken water, such as rapids, cascades, etc., the lines must follow the direction of the flow. To study the finer points of treatment you must examine closely the best etchings and engravings you can find.

In regard to trees, I would remark that if they are in the distance, the small curved lines are the best—a series of little curves forming the outline of the tree or bush. If they are near the foreground, then you must show the character of the tree in the treatment of the trunk,

whether smooth like the beech, or rough like the oak, just as you do in pencil drawing. The foliage is then represented by either the curved or the angular, zig-zag line. In all cases the line must follow the masses of the leaves.

In treating rocks you will find that the rough texture will be obtained best by short, sharp cross-lines.

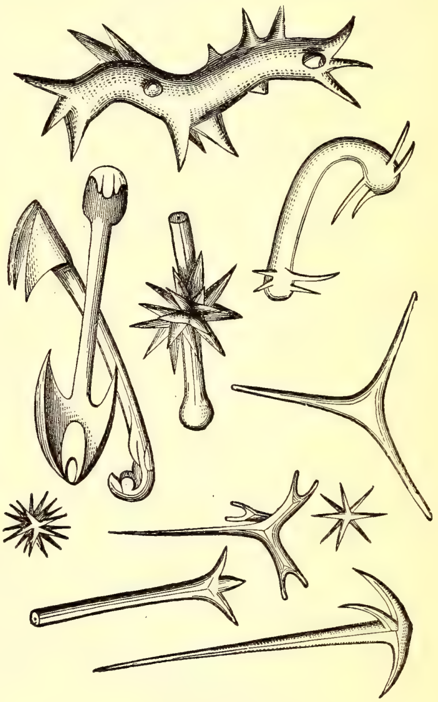
Now it only remains for me to speak of the sky, which with beginners is always a puzzle. It is best to leave it alone until you have gained considerable delicacy as well as freedom of touch. The sky is sometimes the most important part of the whole picture, and I would advise you to make a special study of the manner in which our painter etchers are treating the subject. As a rule, you must either leave it white, or go over the whole space intelligently; not necessarily covering it with lines, but indicating all that goes to make up the effect in outline. If you wish to represent a perfectly clear sky, by lining as engravers do, you must keep the lines close together at the top, and draw them finer and wider apart as you descend to the horizon; but they must be *very* delicate, or you must treat them with stopping out varnish to make them print lightly. In cloudy skies the top is frequently the lighter part, and near the horizon the darkest; but remember that no portion of sky or cloud must be as dark as the shadows on the ground.

[It is, of course, impossible to give an actual illustration of these etchings in the journal, but in a future number we shall give a *fac simile* engraving of a very fine etching, which has been sent to us by Mr. Hartley. This will enable our readers to judge of the capabilities of this method.—ED. Y. S.]

Sponge Spicules.

WHEN our young readers take a sponge in their hands, they probably little think of what it is, and of its curious structure. The common sponge used in the bath-room, is the type of a very large family, the members of which differ widely amongst themselves. Some kinds inhabit our fresh water streams and lakes, but these are generally small, and comparatively few people, even amongst those who have given some attention to the inhabitants of fresh water, are familiar with them. The sponges vary so much in appearance and character that some of them would hardly be recognised as belonging to the same group. Thus, for example, few would suppose that the coarse sponge used by stable boys, and for other rough work, is any relation to the beautiful Venus Flower Basket, which is so prized as an ornament for the mantel piece? and yet they are both sponges.

The beautiful frame work which we know as Venus' Flower Basket, is really the siliceous or flinty skeleton of a kind of sponge, and other kinds of sponges are also provided with these flinty frames, though none are so perfect and beautiful as the one just named. In general the



SPONGE SPICULES.

flinty part of the sponge takes the form of a collection of spicules, and these spicules are found in the most diverse forms, some of which we have figured in the accompanying engraving. Some, as the uppermost one, is simply a rough body armed with spines; others take the form of stars; others of curious club-shaped rods, while others take the form of anchor-

shaped bodies, similar to the curious anchors found in the skins of the so-called sea cucumbers.

It is only in a certain class of sponges that these flinty spicules are found. They are not found in the common sponge, and, indeed, if present there, they would detract greatly from the value of this useful article, which is prized chiefly for its softness and the flexibility and elasticity of its parts. Sponge spicules are often found in a fossil state amongst diatoms, and have given rise to the most curious speculations. They are generally found mixed with diatoms, and have remained after all the fleshy parts of the plants and animals have disappeared.

These spicules are not only curious, but beautiful objects under the microscope, and it is well for those who are beginning the study of objects with this instrument, to become familiar with these curious forms, so that they may be able to know them when they see them.

Editorial Notes

The Close of the Volume.

THIS number brings the third volume of THE YOUNG SCIENTIST to a close, and on reviewing the labors of the year, we feel certain that our unpretentious volume will compare favorably with any similar amount of matter that can be obtained for the same price. Some of our articles may perhaps have been a little beyond the grasp of the average reader, but, on the other hand, we are glad to know that some who began with us three years ago, have made wonderful progress in practical scientific work, and are now able to put in practice things far more difficult than anything we have yet published.

The YOUNG SCIENTIST for 1881, opens with encouraging prospects. We have made arrangements for a large number of practical articles of great value, and we hope to present to our readers twelve numbers of unequalled interest and usefulness. Amongst the articles which we shall publish at an early day, will be one on iceboats and how to make them; a series of elementary articles on the lathe, and how to use it; several practical articles on carpenter's tools; on the use of the microscope, and the preparation of objects, etc., etc. Simple scientific experiments which afford both instruction and amusement, and which are free from danger, will also be a feature of the YOUNG SCIENTIST for 1881. With such a bill of fare we look for a larger subscription list, and trust that all will aid us to achieve this very desirable end.

Postage Stamps.

WE again call the attention of our subscribers to the fact, that while we take postage stamps of small denominations at full value, those of higher denominations are of no use whatever to us. We cannot sell them, except at a very great loss, and the post office will not exchange them for smaller denominations. Therefore, please do not send them.

Removal of Strong Odors from the Hands.

Ground mustard, mixed with a little water, is an excellent agent for cleansing the hands after handling odorous substances, such as cod-liver oil, musk, valerianic acid and its salts. Scale pans and vessels may also be readily freed from odor by the same method. A. Huber states that all oily seeds, when powdered, will answer this purpose. In the case of almonds and mustard, the development of ethereal oil, under the influence of water, may perhaps be an additional help to destroy foreign odors. The author mentions that the smell of carbolic acid may be removed by rubbing the hands with damp flax-seed meal, and that cod-liver oil bottles may be cleansed with a little of the same, or olive oil.—*Druggist's Cirlar.*

Ceresine.—This is a new substitute for beeswax, obtained by chemical processes from a waxy mineral known as ozokerite. It is sold in thin white cakes, and is pure white, scentless, harder than wax, and partially translucent. It cannot be softened in warm water, and is not liable to the action of acids or caustic alkalies. It is volatile at a high temperature, and can be distilled unchanged. For many purposes it will doubtless prove of great value, and it is to be hoped that our dealers will soon have it for sale in this country.

OUR ICE BOAT.

The Young Scientist

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. IV. NEW YORK, JANUARY, 1881. No. 1.

Our Ice Boat.

BY WHIZ.

WE HAD spent an unusually pleasant summer, rowing and sailing on an inland stream. And when Jack Frost came and solidified the glassy surface of our boating place, we, determined not to be deprived of our favorite recreation, built an ice boat.

We had read descriptions of the large ice boats which are used on the Hudson, and on Toronto Bay, but we had never seen one.

Our ice boat was decidedly an amateur affair; it was small and adapted for the limited stretch of ice on which it was used. The mast, sail and rigging were transferred from our sail boat; the skates or runners, were made by a country blacksmith; the wood work we made ourselves.

Our ice boat was a success. With an ordinary wind it carried two persons, and with a stiff breeze, it glided swiftly over the ice with four of us.

With the aid of the engravings, we propose to tell the readers of the YOUNG SCIENTIST how it was built, so that if they wish to try ice boat sailing, they may know how to build a boat for themselves.

The ice boat is, properly, a triangular frame, each angle of which rests on a runner or skate. The main piece in the frame is the centre piece or keel, A C B, as shown in the plan and side view. It is a 3 x 4 inch scantling, set edgewise, and is 16 feet long. 5½ feet of the forward end, C B, is tapered on the under edge and sides, and is rounded so that it is about 1½ inches in diameter at the end B.

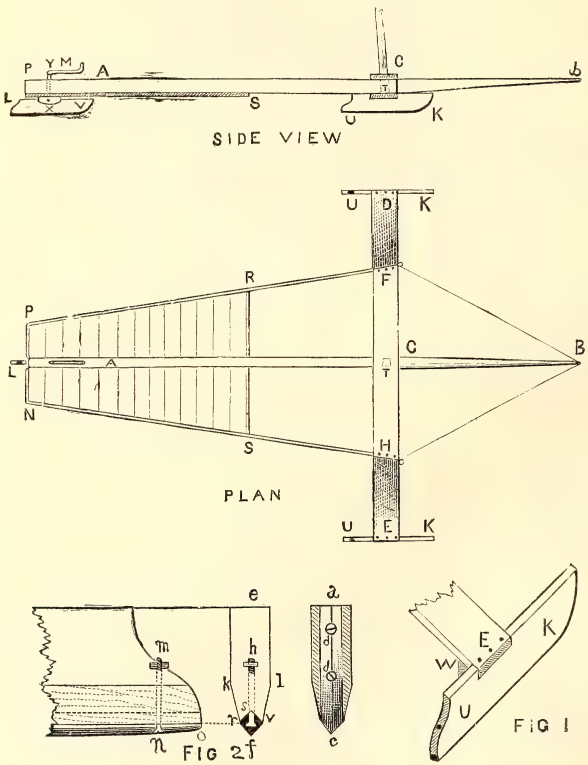
The lower cross piece, D E, is 1½ inches thick, 10 inches wide, and 10 feet long. It is nailed firmly to the under edge of the keel. Its middle point T, being made 6 feet from B, and the distance from T to each of the ends D and E is 5 feet.

The stern, N P, is 1½ inches thick, 4 inches high and 2 feet long. It is nailed at its middle point to the rear end of the

keel. The sides, F P and H N, are each $1\frac{1}{2}$ inches thick, 4 inches high, and about 11 feet long. They are nailed to the stern at N and P, and to the top of the lower cross piece at H and F. The distances T F and T H, being each 3 feet. The top cross piece, H F, is $1\frac{1}{2}$ inches thick, 10 inches wide and 6 feet long. It is nailed to the keel at T, and to the side pieces at H and F.

The mortice, T, to hold the foot of the mast, is made through the top cross piece the voyagers, and the floor should be securely fastened, else they may at some inopportune moment be let unexpectedly down into the ice.

The runners, K U, are each 3 feet long, 2 inches thick, and 7 inches high; they are fastened firmly to the ends of the lower cross piece at E and D, and parallel with the keel as shown in Fig. 1. The cross piece being at right angles with the keel. W is a corner block, which is



down into the keel, care being taken not to weaken the keel by cutting out too much wood.

The piece R S is $1\frac{1}{2}$ inches thick, and 4 inches deep. It is fitted and fastened between the keel and sides about 6 feet from the stern. The space included within R S N P, is boarded on the under side of the keel and sides with $\frac{3}{8}$ inch match boards, fastened with $1\frac{3}{4}$ inch screws. This is the portion of the boat which is occupied by screwed firmly to the runner and the underside of the cross piece.

The bottom edge and forward end of the runner is grooved, as shown at *r s v*, Fig. 2, to hold the iron skate in place. The skate is made of $\frac{3}{4}$ inch square iron, set cornerwise in the groove, as shown at *f r s v*. It is bent up in the shape of a skate or sleigh runner, to fit the forward end of the runner, and is fastened with two $2\frac{1}{2}$ inch screws, as shown at *d d*. The

running edge of the skate is filed away a little at the rear end *n o*, and it is fastened to the runner at *n*, with a quarter inch bolt 3 inches long, as shown at *m n*. The skate should be made slightly concave on its lower edge, so that when it is drawn up, by the bolt *m n*, it will be tight against the entire bottom of the groove in the runner. When it is drawn up into its place, it must be perfectly straight on the bottom or running edge.

Any good blacksmith can make the skates at slight expense. Care must be taken to keep the running edge, *f*, sharp. If any part of it becomes battered it must be smoothed and sharpened with a file. No difficulty is experienced in drilling the holes, *d d* and *n*, through the iron cornerwise, if a flat spot is first filed, so as to start the drill.

The sides of the runners are sloped from the skates to a height of 2 inches as shown at *v l*, and *r k*.

The steering runner V L, is the same length and thickness as the forward runners, but is only about 5½ inches high. A circular block 12 inches in diameter and 2 inches thick, is fastened to the top of the runner as shown at X, so that its centre is directly over the middle point of the running edge of the skate. The tiller shaft, X Y, is a piece of inch round iron about 10 inches long. It is squared and slightly tapered at its lower end so as to fit tightly into a mortice in the block and runner. Its top end, Y, is squared to fit the socket of the tiller, M. The shaft is fastened to the runner by a screw or pin through a hole drilled for the purpose, shown at X.

A one inch hole for the tiller shaft is bored down through the middle of the keel at a point about 12 inches from the stern. A piece of half inch board, 12 inches in diameter, with a one inch hole through its centre, is screwed to the underside of the floor, so that the hole coincides with the hole bored through the keel. The board should be placed so as to afford a smooth bearing for the block on the runner. The hole must be so that the tiller shaft will turn in it easily, and yet not have too much play. If the bearing surfaces are rubbed with a mixture of stove blacking and oil, the friction will be greatly reduced.

The tiller handle must be fitted to the shaft so that it will be exactly in line with the runner. The boat is steered just the same as any sail boat, but it is much more sensitive to the action of the rudder.

The bowsprit is stayed by lines from B to F and H. The mast is stayed by lines to the same points.

When the boat is on a level place, the frame should be level and the entire running edge of each skate should have a full bearing on the ice.

Three Amateur Workers—and What They Did—V.

BY FRED. T. HODGSON.

THE next thing Fred was instructed to do was to joint the board he had "dressed,"—and here let me explain what is meant by "dressed" when used in this connection: "dressed" stuff is that which has been taken from the rough, and planed and made smooth. Stuff is said to be "dressed" on one side, when only one side is planed. When one side and one edge, or both edges are planed, it is said to be "dressed" on one side and one edge, or one side and both edges. And when planed on both sides and both edges, it is said to be "dressed" all round.

To joint the board conveniently, it was necessary to place one end in the bench screw-chops, the other end being held up in place by the movable peg in the side of the bench. In jointing the edge, Fred found that he had to hold the jointer plane somewhat differently than he held the jack plane. The thumb had to rest on the top of the plane, and the fingers were bent under the face to support it, the narrow edge of the board not affording sufficient base to keep the plane steady.

The sole of the plane must be kept at right angles with the side or face of the board whilst jointing. The reason of this is quite clear; for it must be evident that if the joints of two boards are to fit with their edges together, they will not

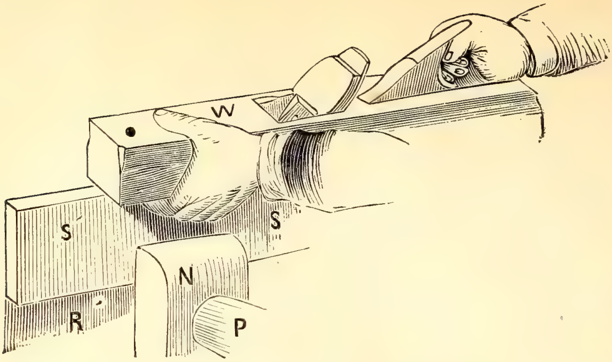


Fig. 18.

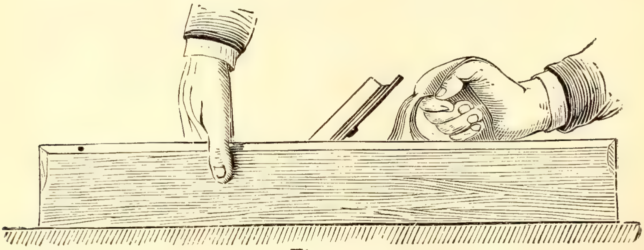

Fig. 19.

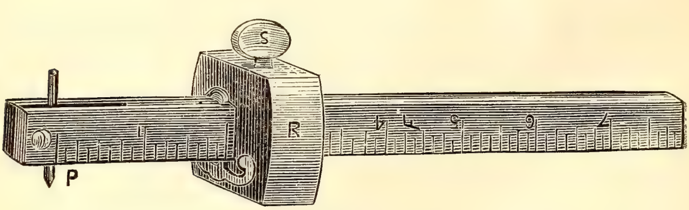

Fig 20.

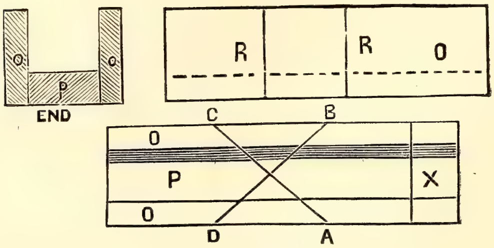

Fig. 21.

Fig. 18 shows the method of holding the short jointer or fore plane, when jointing thin stuff. S S, is the stuff being jointed, N the screw-chops. P the screw head, R the bench, and W the fore plane.

NOTE.—An absolutely true surface is a theoretical impossibility, though surfaces are made so true that the most accurate measurements are not capable of discovering their defects.

Fig. 19. This cut shows how the long jointer should be held when jointing or truing stuff.

Fig. 20. shows a common gauge. R is the head. F the stem. P the spur. S the tightening screw.

Fig. 21 shows the end, side and plan of the mitre box. O O and P shows sections of the sides and bottom, C. A. B, D, show how the box is cut for a mitre. X shows how it is cut for a square cut. R, R, O, show the side, with the cuts.

form a fair surface if the jointing edges are not square as well as straight.

Mr. Carpenter fully explained this matter to Fred and Ellwood, and both boys seemed to understand their father quite well; so after instructing them a little further in the use of the three planes and the two saws, he took from a shelf, where he had previously placed it, another plane much larger than either of the ones the boys had been using. "Now," he said, "I will show you how to use this long plane; though, in your amateur work, you will not have much need to use it, for the short jointer will nearly do all the jointing you will have to do."

"Is that the long jointer, Pa?" said Ellwood.

"Yes," said Mr. Carpenter, "this is a long jointer, and great care must be taken of it, for it is so long that it is easily warped or twisted on the face. It is chiefly used for jointing long stuff, and in the hands of a good workman is capable of doing good service. When this plane is as near "true" as it can be made, and the iron is in proper condition, it can be run along the edge of a board four or five feet long, and if it takes off a fine ribbon shaving from end to end without a break, the edge is as nearly straight as it can be made, providing it was first hollowed out a little, for you can see, that if the edge was slightly rounded, or high, the iron could cut it, even if the wood of the plane did not touch the edge."

"If I hold this plane in a similar manner to the way I hold the short jointer, won't it be all right Pa?" said Fred.

"Well," said Mr. Carpenter, "some persons do hold the long jointer the same way they hold the shorter one, but I don't think they get such good results when they adopt the latter method. You will soon discover which method suits you the best, and, of course, that is the one you will adopt."

"I think," he continued, "that you are pretty well informed as to the use of the bench planes now, so far as regards ordinary work. As you proceed, new conditions will arise in which the plane will be made to perform work under somewhat different circumstances than the ones we have been discussing, and when they do, I will show you how to use the tool in such a way that the conditions will be fully met; in the mean time we will take up some other matter."

"One of the first things you will require," continued Mr. Carpenter, "is a mitre box."

"Very well," said Fred, "if you will show me how to make one, I will commence at it at once."

"To make a good mitre box," said Mr. Carpenter, "you will require two sides made from inch stuff, five inches wide and two feet four inches long. Dress these up nicely, and guage them to an equal thickness and width. You see this gauge, it is figured in inches and eighths of an inch, the spur being on the first mark. The head is movable, and can be made fast at any point by the wooden thumb-screw. When you have made a straight edge, or planed one side of a piece of stuff true, you can set your gauge to the width or thickness required; then fasten the head in place, and press the head against the planed edge or side, and the spur will mark off the desired thickness or width."

"Now then," Mr. Carpenter continued, "you have got the two sides ready; now get a piece of stuff two feet four inches long, and four and a half inches wide, and one and a half inches thick. True it up, and make it square. This is for the bottom piece. Now nail the two sides on the bottom piece, keeping the ends all even. Now you have a box without ends or top; to make it into a mitre box, you must square across with the steel square I bought you, and the uses of which I will explain to you some other time. Mark with a knife, then take the exact distance across the box; meas-

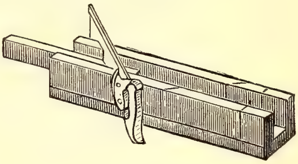

Fig. 22.

Fig. 22 shows how the saw kerfs may be cut if desired. Some workmen like this method, others like the one shown at Fig. 21.

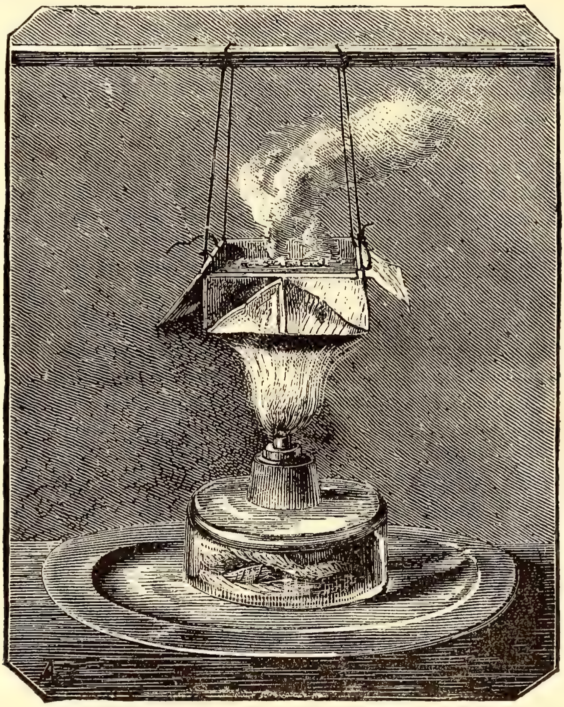
ure that distance on the side of the box from the line already made, then square across the box again. Now mark across the top of the box diagonally from point to point of the knife marks already made. These lines form a square mitre, or an angle of 45 degrees. Square down the sides of the box; now saw down until you strike the bottom of the box, minding to keep close to the lines, or the work will be but indifferently done. Now we have a mitre box that will do us a good deal of service. We can make it more useful by cutting a square cut in it at one end. This will do very well where we want to cut stuff square on end. The box can be used for many other purposes as I will show you as we proceed."

(To be continued.)

—To enlarge a hole in a glass plate, use a fine rat-tail file with a little turpentine and camphor. If the hole is nearly the size of the file, the latter will stick and break the glass plate, if it be turned round from left to right, but not if it be turned from right to left.

Science of Common Things.—Fire and Water.

FIRE and water have long been recognised antagonists, and, although water may be apparently made to burn, yet the general effect of water when thrown on burning bodies is to put out fire. This it does by cooling them below the point at which they burn, when, of course, the fire goes out. A very simple and interesting illustration of the reason



WATER BOILED IN A PAPER BOX.

why water quenches fire is shown in the accompanying engraving, where water is being boiled in a paper vessel. To perform the experiment, make a box out of stiff close-grained paper, by folding up the sides and ends and turning over the corners in a manner well known to children. Such a box when filled with water may be suspended by four threads from a horizontal rod, and if placed over a lamp, as shown in the figure, the water will soon boil. No fear need be entertained that the paper will burn; the water prevents

this completely. In our next, we shall tell of other methods of heating water in vessels which are not usually supposed to be capable of resisting fire.

Crystals Under the Microscope.

AMONGST the favorite objects of the early microscopists were crystals of different salts. Baker, in his book, "Employment for the Microscope," describes almost all the salts at that time known, and he even attempts to identify various plants by means of the different appearances of the crystals formed by the salts obtained by leaching their ashes. And even now, when the young microscopist has not succeeded in procuring a good "find" of microscopic plants or animals, a few of the more easily procured salts will furnish a great deal of pleasant and instructive amusement.

Crystals may be easily mounted for preservation and further examination, but it will be found that altogether the most interesting sight is the actual formation of the crystals under the eye of the observer. For this purpose a little nitre, sal ammoniac, or any other salt that crystalizes in needle-shaped or feathery crystals, gives the most beautiful results. A little of the salt having been dissolved in water, a drop is placed upon a well-cleaned slide (which has been slightly warmed) and spread evenly in a thin layer. No cover glass is used as we wish the liquid to evaporate quickly. The slide having been placed upon the stage of the microscope in a few seconds crystals are seen to form and shoot out over the entire surface of the field of view. The scene of minute forest growth cannot be described; it is too surprising and beautiful. Fortunately, however, the experiment is so easily tried that any one that has a microscope can see it for himself.

One word of caution may be necessary. In very cold weather the microscope should be warmed so that the moisture from the slide may not condense on the lenses of the microscope and dim them.

Some salts crystallize in very curious forms. Thus salicine takes the form of beautiful circles, with rays proceeding from the centre. The same is the case with the compound formed of iodine and sulphate of quinine, and when crystals of salicine or quinidine are viewed by polar-

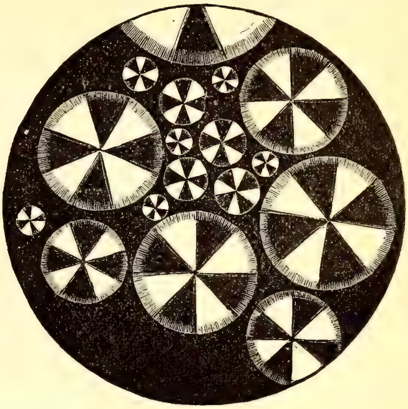


Fig. 1. CRYSTALS OF QUINIDINE SEEN BY POLARIZED LIGHT.

ized light, the sight is a most beautiful one. The entire field is seen to be filled with circles, each containing a little cross, which, as the polarizer turns, revolves like a little wind mill. When, in connection with the polarizer, a selenite plate

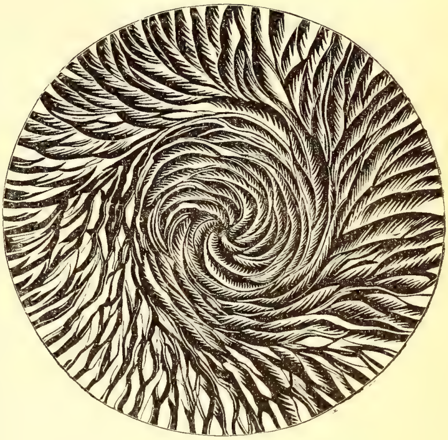

Fig. 2. SPIRAL CRYSTALS OF SULPHATE OF COPPER.

is used, the sight is one of the most beautiful that can be imagined. The little crosses shown in Fig. 1, instead of being black and white, are gorgeously colored with red and green, blue and yellow.

When pure solutions of salts are mixed

with gum or similar matter, they sometimes crystalize in very curious forms. Fig. 2, shows a form sometimes taken by sulphate of copper, under such circumstances. The reader will observe the curious spiral form assumed by the crystals, and it will be well to compare them with crystals formed by a pure solution of the same salt.

Mixtures of different salts also give rise to curious combinations of crystalline forms. Thus a mixture of sulphate of copper and sulphate of magnesia crystallizes in a manner that is both curious and beautiful.

Of all the crystallizations which can be readily produced, however, none equal in brilliancy and beauty that of pure silver. But to be seen in perfection the crystals must be watched during the process of formation; when mounted, even in their best condition, they fall far short of the appearance which they present while growing. The method which we have found to give the best results is to place a drop of solution of nitrate of silver on a slide, and bring in contact with it a small mass of the amalgam used for ordinary mirrors. The drop of liquid should be well spread out and the glass should be black. If black or dark colored glass cannot be procured, a piece of black paper may be pasted on the under side of an ordinary slide. As soon as the amalgam has been brought in contact with the solution of silver, decomposition takes place, nitrate of tin and mercury formed, and pure silver is thrown down. This pure silver instantly forms, with the other substances present, a minute voltaic battery and the rest of the silver is deposited in beautiful crystals just as copper is deposited on one of the poles of the Daniel's battery. These crystals shoot across the field with considerable rapidity, and they are seen to grow in exquisite fern-like masses, of which our engraving gives a faint representation. While fresh, their surfaces are clear and brilliant, and if well illuminated by means of the bulls-eye condenser, or any similar method of condensing light on them, they are almost dazzling. An objective and eye-piece of low power should be used, a magnifying power of thirty diameters being sufficient.

We prefer the amalgam of tin and mercury to all other agents for throwing down the silver, because it does not interfere with the beautiful white color of the crystals, as do copper and most other metals. When a greenish hue is desired, however,

Fig. 3. CRYSTALS OF SILVER.

copper or brass may be used. When the solution becomes weak, the crystals form in slender, needle-like stems; when the solution is strong, the silver is deposited in frond-like masses. By varying the strength of the solution during the process of crystallization, the most beautiful effects may be produced.

Home-made Telescopes and Microscopes.—XII.

ON THE OBSERVATIONS REQUISITE FOR CORRECTING OBJECT-GLASSES.

FOR this purpose, a particle of mercury is placed upon a slip of black glass. A piece of watch-spring, or the thin handle of a spatula, is held up at its end by the fore-finger of the left hand, and slapped down on the mercury, which is thus beaten into powder, in the form of numerous minute globules. Of these, a larger size is selected for correction of color, and a minute one for ascertaining the errors of figure and centering, and state of the oblique pencils.

The globule must be illuminated by direct candle or lamp light, and not by daylight, as the latter will not allow per-

fect correction to be obtained. The light requires to be set as close as it can be, and, of course, in the highest powers, where there is little distance in front, it must be very oblique; but this is of no consequence, as it is not the globule itself, but the spot of light reflected from it, that is required to be seen.

The lens to be tested is adapted to the microscope, having the ordinary Huyghenian eye-piece. On placing the globule either in or out of focus, the luminous point expands into a ring. If the object-glass is under-corrected for color, as in a single lens, the bright ring appears within the focus, the outer margin is red, and the inner circle green. If the lens is over-corrected, the bright ring appears *without* the focus, with the colors in the same order as before. A practical knowledge only, derived from these appearances, can determine the amount of concavity to be given to the flint, or difference of convexity in the crown, for obtaining the desired correction; but even in the most experienced hands it generally involves several alterations to secure perfect achromatism. When this is corrected as far as practicable, a pale-green color only is perceptible beyond the focus. This arises from the secondary spectrum, or relative difference in the width of the prismatic color spaces of the crown and flint, and seems to be a variable condition, according to the composition of the glass employed.

Though correction for spherical aberration is intimately related to that of color—a single lens when finally achromatised, being also nearly free from spherical error; yet, in a combination of three pair, when matched so as to be achromatic, this may be so considerable as to render the object-glass useless, and is oftentimes exceedingly troublesome to remedy. The error may arise from an improper proportion between the relative foci of the lenses—as the back being too long. I have before stated that, in the form that I have advocated, the spherical aberration is mainly corrected by giving thickness to the front lens, and by properly adjusting the distance between them. In a glass spherically under-corrected the light from the globule is greatest within the focus, and when set out of focus speedly vanishes and becomes diffused; in the case of spherical over-correction the contrary appearances result. When the relative distance of the lens is rightly adjusted, the light spot expands equally, and is of the same intensity, for a short distance on either side of the focus, in which the globule should appear with a clear bright margin. The object-glass is now in a proper condition for testing errors of construction and workmanship.

To examine the condition of the oblique pencils, and consequent flatness and distinctness throughout the field, a small globule is selected, and brought to the edge, using the lowest eye-piece; if the bright point in the centre of the globule, when a little out of focus, approaches to the inner side of the concentric light-rings, as in Fig. 20, it is termed "outward coma," and indicates that the front incident surface of the back triple is too *convex*. If, on the other hand, the bright spot is on the outer side of the rings, or next the margin of the field of view, there is "inward coma," which shows that this same surface is too flat. I have previously remarked that this curve has a powerful effect on the flatness of field and perfection of oblique pencils, and for these no other correction is generally requisite than an alteration in this radius.

Before the glasses are finally cemented in their cells, they should be carefully tested for centering; for this purpose a very minute globule is selected, and placed exactly in the centre of the field. If the bright spot appears eccentric, with the rings thus (Fig. 21), the pair of lenses which occasion the error should be shifted on each other while warm enough to cause the Canada balsam by which they are cemented together to yield, till on repeated trial the error is corrected. This is important, as the least fault of centering materially impairs the performance of an object-glass. But with the precautions that I have adopted in the construction, already explained, errors of centering cannot occur.

There is yet one other globule test for object-glasses, to indicate accuracy of

workmanship, or whether the lenses are worked to true spherical surfaces. If the rings from a minute globule appear of an irregular wavy outline, as shown by the annexed cut (Fig. 22), either approximating to a polygon or triangle, it shows that one of the surfaces at least that refracts

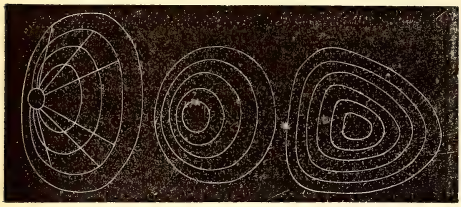

Fig. 20. Fig. 21. Fig, 22.

the rays is of this form. Such workmanship is inexcusable, and those that cannot avoid it had better let glass-grinding alone.

Finally, there is an appearance that I have sometimes seen in our best object-glasses, when focussed away from a globule, viz., "Newton's rings;" this shows that in the contact surfaces of one of the pair of lenses, the convex is deeper than the concave, and bears hard in the middle. This may have no worse effect than loss of light; but still it is as well avoided.

Gravitation Converted into Home Attraction.

BY A. W. ROBERTS.

WHAT shall we do to-night, little folks? Tell stories, or make something?"

"Oh make something! make something, Papa!" was the general reply.

"What shall it be?"

"Make a 'grunk man,' what the side-walk jumped up and made the bleed come, so that he had to sit down till the soger man came around and took him to his mother."

We all laughed at little "Dumps" request, which I promised to grant.

"Now, then, bring forth your 'trumpery' as Mamma calls it, and we will see if there is a sufficiency of uselessness to construct a drunken man out of."

Cast aside slate sponges, crooked sticks, tissue paper, beeswax, shells of English walnuts, some old water colors, a piece of lead pipe, two tumble bugs, and a "hoppy toad," which Ned informed me he had kept for three days hidden under the lounge, and I musn't tell Mamma nor Bridget. From these, was to come forth a terrible example of intemperance.

For a correct likeness of the drunken man the reader is referred to Fig. 1, which

Fig. 1.

was made in the following manner: The shells of an English walnut were fastened together with beeswax, after which a hole was bored through the smaller end to admit of a stick of wood, six inches long, and pointed at the end, which was then fastened in the hole with hot wax. Another piece of wood five inches long, the ends of which curved upwards was fastened to the first stick, two inches below the nut, with thread.

With plaster-of-Paris and a piece of lead pipe, I was to cause this forthcoming man to reel and tumble about, as if greatly demoralized.

Mixing the plaster to a thick paste, I placed a layer half an inch thick in a small bowl, well greased with lard to pre-

vent the plaster from sticking. When this was set, a flattened-out piece of the lead pipe was placed in the centre of the plaster. The bowl was then filled to the rim with more plaster, when the remaining end of the six inch stick was inserted in the centre of the plaster before it set, as shown by the dotted lines in Fig. 1. After the plaster had set, I withdrew it from the bowl, and while still moist, shaved down with a pocket knife the too conical end of the half sphere of plaster, taking care not to shave into the piece of lead. I then went over it with sandpaper. The ends of the cross stick were dipped into soft plaster, and when this had set, they were carved to resemble hands.

The nut, upright and cross sticks, formed a rude head, body and arms, which was dressed with tissue paper fastened together with boiled flour paste.

The walnut was then painted flesh color, the features were drawn in with writing-ink, and a ruddy complexion was given by vermilion.

The hair and beard were composed of the downy parts of chicken feathers stuck on with warm wax.

When all was finished, great was the astonishment of the children, over this image that couldn't lie down, but went reeling and rocking across the table, Little Dumps looked scared, and whispered " Are it a gunk man for truly ?"

I had no idea what industrious collectors little folks are till next evening, when I was brought face to face with a small sized mountain of " trumpery " that consisted of the loaned collections of all the children on the block. I learned that my glory as a toy maker had spread, and that my last night's effort had been on exhibition all day on the front stoop to an admiring crowd, and to the dismay of Bridget, who had to " clane up the clutter after thim."

Out of this miscellaneous gathering I constructed the monkey as shown in Fig. 2, which was composed principally of old sponge slate cleaners, and was a sort of irrepressible pen-wiper, which, the children christened the "Chimpansee," pen wiper, and declared it to be so pretty, when finished, that it must be placed on the nic-knackery stand.

It was made in the following manner: Selecting the largest size piece of sponge,

Fig. 2.

I cut it into the form of a monkey's body, clipping it smoothly with a pair of scissors. Then a head was made the same way, also a pair of arms and legs and tail. These different parts were then gone over with a red hot poker which charred the surface of the sponge, so that it was easy to shape the parts more perfectly by scraping the surface away with a knife. This application of heat also gave the sponge a rich brown color. The several parts were then fastened together by passing a double-threaded needle through them.

After the body was finished, the eyes and mouth were painted in. It was then fastened to a lead button. The button was cast in a mould of yellow soap, which was made by boring into it with a teaspoon. When the lead button came out of the mould it was ridged, and rough, till sandpapered off smooth, after which the bottom was ground flat; this was to cause the monkey to rebound quickly to the upright position. The latter was fastened to the body of the monkey with hot wax, after which it was varnished with black asphalt varnish.

The next article made was a magic bottle, shown in section in Fig. 3. Taking a piece of wood, I shaved it into the form of a bottle with a very long neck, this was then thoroughly oiled. After which strips of tissue paper moistened in water were wrapped compactly around the bottle, and between each wrapping boiled flour paste was applied thinly.

The neck part was formed by folding and pressing the wet tissue about the neck of the wooden shape, using plenty

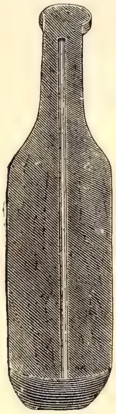

Fig. 3.

of paste to fasten the folds securely together. The paper wrapping was then dried and coated with black asphalt varnish. After the varnish was dry, the wooden shape was slipped out of its paper covering. A leaden button cast in a soap mould was closely fitted to the inside of the paper wrapping and fastened with hot wax, so as to form the bottom of the bottle.

This bottle presistently stood up, no matter how flatly it was laid down.

To cause it to lie down I used a small piece of iron, which I palmed in my hand,* and whenever I wished the bottle to lie down, I slipped the wire into it. To cause it to stand up, I dropped the wire into my hand, and palming it, I passed the bottle to the children. They, of course, failed to make it lie down, so that they were completely mystified. Sometimes I pretended to take a drink out of the bottle, and slipped the wire into my mouth, again passing it back when I wished the bottle to lie down. At last they gave it up, and I explained to them the action of gravitation, as I propose to do to the readers of the Young Scientist, in my next article.

* For an explanation of the method of "palming" objects, see "Lessons in Magic"—Young Scientist, vol. i, p. 139.

To Make a Magnet Out of a Poker.

At first sight this seems a wonderful feat, and yet, when we consider that we have always at hand the most powerful magnet of which we have any exact knowledge, it is not so surprising after all. The magnet to which we refer is *the earth*. Perhaps all our readers do not know that the earth is a magnet, but we can assure them that such is the case, and that it is solely by its magnetic force that all the magnetic needles in the world are made to point to the north. And it is further a fact that this great magnet, the earth, induces magnetism in every piece of iron lying on its surface. When a long piece of iron is placed in such a position that the poles are formed very close together, then the magnetism that is manifested is very weak, but when the poles are formed in the extreme ends of a long piece of iron, the magnetism is sometimes so strong that good sized nails may be lifted.

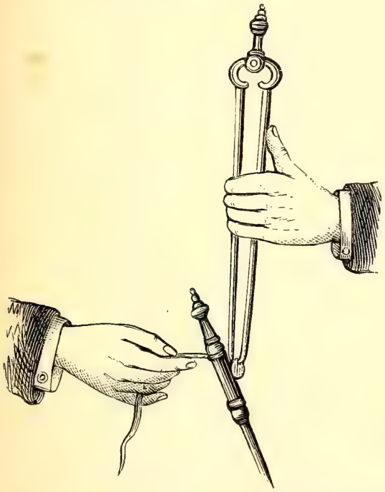
Now, for this purpose, the best position of the piece of iron is when the longest diameter lies parallel with the magnetic axis of the earth. The magnetic axis is not exactly the same as the astronomical axis, but it will be found that when a rod of iron stands so that it points to the north pole, it always gives pretty strong indications of magnetism. Even when held exactly perpendicular, a long iron rod becomes a powerful magnet, and hence, the iron tubes used for drive wells are always magnets. This is the true explanation of the notorious "magnetic wells."

If a poker be held upright and tested with a needle (a common charm compass will answer,) it will be found that one end repels, and the other attracts, each pole of the needle, thus showing that it is a

magnet, so that to redeem our promise to make a magnet out of a poker, all we have to do, is to tell our readers to hold it upright. But, unfortunately, the magnetism is weak, and as soft iron does not retain the magnetism which is imparted to it, as soon as we change the position of the poker, the magnetism is weakened to such a degree that we can hardly detect it. By the following method, however, we can easily make a permanent magnet out of a small piece of steel.

Such a piece of steel is easily procured; a piece of an old file answers very well, but a piece of well-worked steel which has been made as hard as possible, is neater and better. Having procured such a piece proceed as follows:

Take a poker and tongs, or two bars of iron, the larger and the older the better, and fixing the poker upright, hold to it with the left hand, near the top, by a silk thread, the bar of steel, of which the magnet is to be made, the marked end being downwards. Then, grasping the tongs with the right hand, a little below their middle as shown in the figure, and



MAKING A MAGNET WITH A POKER AND TONGS.

keeping them nearly in a vertical line, let the bar be rubbed with the lower end of the tongs, from the marked end of the bar to its upper end. about ten times on each side of it. By this means the bar will receive as much magnetism as will enable it to lift a small key at the marked end; and being suspended by its middle, or made to rest on a point, this end will turn to the *north*, and is called its *north* pole; the unmarked end being the *south* pole.

How to Hang a Thermometer.

THE recent cold weather has called general attention to this subject. The great differences in the readings of thermometers hung up a short distance from each other, show either that the majority of thermometers are incorrect, or that they have not been subjected to the same influences. In general, the temperature that we desire to get is that of the surrounding air. Too often, however, we get the temperature of the clear sky, or of some wall or building which is either much colder or much hotter than the air. The temperature of the wall of any building, at any hour of the night or day, is not the true temperature of the circulating air, and is of no use to science. A wooden wall becomes cold more rapidly than one of brick or stone, and the amateur scientist who hangs his thermometer on a wooden wall can force his mercury down below the amateur who selects a brick wall. The proper way to expose a thermometer is to surround it with a light wooden frame, covered with slats, like shutter work, and roofed over. This will protect it from the direct rays of the sun and reflected heat. Run a light bar of wood across the centre of your shelter, to which the thermometer may be attached. This should be on the north side of the building, and at least one foot from all surrounding objects.

The effect of a clear sky during a cold night in depressing the thermometer, is something extraordinary. A simple screen of cloth placed between the thermometer and the sky, though at some distance from the former, will make a difference of several degrees in the result. Fortunately the bright bulbs of ordinary thermometers do not radiate heat very rapidly, and so the effect of this influence is not felt as severely as it might otherwise be. But if we blacken the bulb so as to increase its radiating power, and then expose it to a clear sky, the fall will be something remarkable.

The fact that the bulb of the thermometer, in its usual bright condition, neither radiates or absorbs heat rapidly, is a most valuable and important one. It is best seen in the case of the rays of the sun falling quickly on the bulb. Ordinarily this makes a change of but a few degrees—15 to 30 at the most. But when the bulb is blackened, a difference of 100° to 150° may be seen between shaded and unshaded thermome-

ters! Some years ago we tested this very carefully, and found that while a thermometer, screened from the rays of the sun, showed but 9° above zero, a similar thermometer, with the bulb blackened and screened from draughts of air, showed 165°!!

A Lubricator for Whetstones.

A French journal suggests, as a substitute for oil in sharpening tools, a mixture of glycerine and alcohol. The proportions of the mixture vary according to the instrument operated on. An article with a large surface, a razor, for instance, sharpens best with a limpid liquid, as three parts of glycerine to one part of alcohol. For a graving tool, the cutting surface of which is very small, and the pressure exercised on the stone in sharpening very great, it is necessary to employ glycerine almost pure, with but two or three drops of alcohol.

A Brilliant Coating for Ornaments.

The appearance of articles manufactured by amateurs, and intended for mantel-piece and other ornaments, may often be greatly improved by coating them with the following preparation: Plates of mica are first rendered perfectly clean and white, either by boiling in muriatic acid or by igniting them; they are then washed, dried, and ground to a fine powder, which is thoroughly sifted and mixed with very thin collodion. In this condition it is applied, like paint or varnish, with a soft pencil, two or three more coats being given to the article until the desired thickness is obtained, which is determined, of course, by the taste and judgment of the workman. The objects thus coated have a silvery appearance, and possess the valuable advantage over those in which the ordinary metallic bronze is employed, of not being at all affected by sulphurous vapors; neither are they injured by dust or dirt, and are readily cleaned by washing in water. Collodion adheres firmly to glass, porcelain, wood, metal, and pasteboard; and as mica is capable of taking any desired color, at the same time retaining completely the lustrous appearance distinguishing it, it furnishes by this process an exquisite covering for a large variety of articles.

Doing Much.

Many persons seem always to be in a hurry, and yet never accomplish much; others never to be hurried, and yet do a great deal. If you have fifty letters to answer, don't waste time in looking over and pondering which one you will answer first; arrange them without much thought in the order of their importance, and then go through the whole pile. Some begin a thing, and have it partially completed, and hurry off to something else. A better plan is to complete whatever you undertake before you leave it, and be thorough in everything; it is the going back from one thing to another that wastes valuable time. Deliberate workers are those who accomplish the most work in a given time, and are less tired at the end of the day than many who have not accomplished half as much; the hurried worker has often to do his work twice over, and even then it is seldom done in the best manner, either as to the neatness or durability. It is the deliberate and measured expenditure of strength which invigorates the constitution and builds up the health; multitudes of firemen have found an early death, while the plow boy lives healthily and lives long, going down to his grave beyond three score and ten.

French Polishing.

This operation requires practice to ensure success, but is easily acquired. The surface of the wood should be thoroughly smooth, and the grain well filled. Rub down with finest sandpaper until of a uniform greyish tint, without scratches, and remove dust with a dry warm cloth. Make a wad of flannel or wadding; saturate this with French polish, and wrap in an old piece of printed cotton or soft rag. Touch the rag with two or three drops of raw linseed oil, and rub the work in a circular direction. Do not allow the rubber to stick. When the surface is well bodied in, finish off in the same manner, but with two-thirds polish to one-third alcohol. In other words, thin the polish in the rubber every time it is saturated, until the wood is as bright as plate glass. Twenty-four hours should elapse before the finishing process is commenced.

Working Hard Metals.

Metal workers know that some alloys are very hard to drill or turn in the lathe. So are phosphor bronzes, the aluminum bronzes, and even the alloy of 7 parts zinc, 4 of copper, and 1 of tin, with which a Paris mechanic lately experienced much difficulty. He remembered, however, that even hard glass may be cut with a good steel drill when it is lubricated with turpentine, and so he tried this on hard bronze with good success. The best material he found to be petroleum, mixed with turpentine spirits, with the help of which the tools, which otherwise soon became blunt, retained their cutting edges. He found that even hard steel, only slightly tempered to a straw-yellow, could be easily cut in this way with good chisels and drills made rather harder than usual.

Feeding Terrapins.

THE *Washington Globe* tells us that in one of the fish-ponds of the Smithsonian Institution at Washington, some twenty varieties of terrapin have been kept for purely scientific purposes. It was the custom to feed them on such interloping fish as disturbed the fish-cultural economy of other preserves. A low goldfish, a hybrid trout, a carp of impure race, would be thrown to the terrapins. Sometimes these fish were eaten, but mostly were haughtily disdained. One day this Spring, a gardener who had been cutting the blooming clover, filled his barrow with the fragrant load and trundled it over a plank. He made a misstep and dumped his clover into the terrapin pond. In an instant the water was in a commotion. Every terrapin, no matter whether from Long Island Sound or the Gulf of Mexico, was seen busy devouring the clover. Like Elia's roast pig, the secret of feeding terrapins was discovered. Learned and grave Smithsonian professors chuckled over it. During the past Summer the daily allowance for the Smithsonian terrapins has been a barrow-load of sweet clover. This hint may be of service to those who keep these animals as pets in aquaria or elsewhere.

Practical Hints.

Shop Counters may be cleaned by the use of the following mixture, which must be sparingly applied by means of a rubber of cotton: Linseed oil, 1 pint; alcohol, 4 ounces; acetic acid, 4 ounces; spirits turpentine, 4 ounces; muriate of antimony, 1 ounce.

Mucilage for Mineralogical Specimens.—This cement is described as invaluable for mending fossils and minerals, and for attaching labels to them, being very adhesive and never becoming brittle or scaling off. Starch, two parts; white sugar, eight; gum arabic, sixteen parts; water, sufficient. Dissolve the gum, add the sugar and starch, and boil until the starch becomes transparent.

Cement for Broken Delf or China.—The following cement dries rapidly, so that in two or three days the mended articles are quite firm, while with oil or varnish cements (such as white lead) weeks are required. Make a thick solution of gum arabic in water, then stir in plaster-of-Paris until the mixture becomes a sticky paste. Apply with a brush to the broken edges, and stick them together.

To Save Articles from Rats.—Rats are accomplished rope-walkers, and are able to make their way even along very small cords. Consequently, so long as they can mount upon the lines, nothing edible suspended therefrom is safe from their attacks. Perfect security may be attained by using wires, upon which circular pieces of tin are strung, the meat, grain etc., being hung between the tin pieces. The rats cannot pass the tin circles, because, as they attempt to climb over them after walking out on the wire, the pieces revolve.

Painting Gilt Paper.—We wished to paint, with water colors, a monogram on gilt paper, but could not get the paint to lie, not even when mixed with gum; it either scaled off, or was patchy. After trying various expedients, we scratched all over the surface of the monogram with a hard lead pencil, and we then found that the water colors could be easily painted on the surface. Their effect on the gold ground was very great, and perhaps some of our "illuminating" readers may thank us for illuminating them with this "wrinkle."—*Printers' Register.*

Lamps With Colored Flames.—It is said that glycerine may be burned in any lamp so long as the flame is kept on a level with the liquid. The latter, on account of its viscidity, will not ascend an elevated wick. As the flame, like that of alcohol, is almost colorless, and as the material is especially adapted for dissolving a large proportion of saline substances, M. Schering has recently made experiments in coloring the flame with various bodies, and with satisfactory results. By introducing substances rich in carbon, it appears that the flame may be rendered suitable for illuminating purposes.

Hot Sand as a Bed-Warmer.—The good effect of hot water or a hot brick when placed in bed with persons who are weak or sickly, is well known. A bottle of hot water is a general favorite, but something quite as good, and a great deal more pleasant, is a bag of hot sand. Get some clean, fine sand, dry it thoroughly in a kettle on the stove, make a bag about eight inches square of flannel, fill it with the dry sand, sew the opening carefully together, and cover the bag with cotton or linen cloth. This will prevent the sand from sifting out, and will also enable you to heat the bag quickly by placing it in the oven, or on the top of the stove. After once using this you will never again attempt to warm the feet or hands of a sick person with a bottle of hot water or a brick. The sand holds the heat a long time, and the bag can be tucked up to the back without hurting the invalid. It is a good plan to make two or three of the bags and keep them ready for use.

To Write Permanently on Glass.—The surface of the glass is gently heated over an alcohol lamp, or Bunsen gas-flame, until the vapor of water ceases to condense upon it, when it is to be coated with a varnish made by dissolving 8 grammes of sandarac and 4 grammes of mastic in 80 grammes of alcohol (95 per cent.) The solution is easily effected by heating the ingredients in a flask. It forms a varnish which is very hard, and ought to be completely transparent; if the surface over which it is poured is cold, it becomes opaque.

The glass surface coated in the manner described may now receive any design or sketch drawn upon it with ordinary ink or india-ink. It is then covered with a film of any non-alcoholic varnish.

This process may be advantageously employed as a substitute for the labels commonly used on bottles in the laboratory and elsewhere, to draw or trace sketches on glass for magic-lantern projections, etc

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

Wanted back numbers of "American Naturalist" and "American Journal of Science and Arts" (Silliman's Journal), for beautiful specimens, named, of American ferns, mounted or unmounted. Box 16, Pine Plains, N. Y.

Wanted, to correspond with some one living near the ocean beach; also some one living near any lead or copper mines. Ewing McLean, Greencastle, Ind.

Beautiful Beryls, Garnets, Tourmalines, Rose Quartz, Muscovite, Granites in variety, etc., to exchange for coins, shells, fossils, minerals, books, magazines—anything. Describe offers fully. C. Le R. Wheeler, Wilmot, Merrimack Co., N. H.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

Wanted, specimens metallic ores; will give in exchange fossil shells, Vicksburg epoch, Tertiary period; state kinds of ore. Philip Crutcher, Warren Co., Vicksburg, Miss.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing, P. O. Box 178, Wattsburg, Erie Co., Pa.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

I have some stamps which I will trade against other stamps, or offers; please send list of stamps you have to exchange. J., 226 West 22d St., New York.

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

Wanted, a household microscope, telescope, large lenses, well-mounted slides for the microscope, books on the microscope or entomology, in exchange for stuffed birds or minerals; describe offers, and state what is wanted in exchange. E. O. Tuttle, Hampden, Mass.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J,

Minerals to exchange for other minerals; state what specimens you have for exchange. Samuel Wynne, Box 54, Phoenixville, Pa.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa,

I have a four-legged and four-winged one-headed chicken, in alcohol, which I should like to exchange for a good breech-loading shot gun, or for standard scientific books. A. H., Box 500, Albion, Ohio.

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Wanted, scientific books, minerals, fossils, and Indian relics, in exchange for minerals, fossils, coins, old Continental and Federal money over one hundred years old (very rare), foreign stamps, A. W. Baily, Box 712, Atlantic City, N. J.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Idaho Mineral Specimens, for bound books on science, travels, history, biography, political, masonic, and others that are instructive. J. P. Clough, Junction, Lemhi Co., Idaho.

I have minerals (including fossils and dentrites), to exchange for minerals; also a papyrograph outfit, without press (worth $25), for offers. W. H. Eastman, Hyde Park, Mass.

Klose's celebrated "School for the Clarionet," new, $3; will exchange for telescope, microscope, piccolo, books, or offers. Rush Holbrook, Wonewoc, Juneau Co., Wis.

One or two handsomely mounted red deer heads, attractive ornaments for any dining-room or hall, for microscope, telescope, sporting implements, camping outfit, scientific books, or offers. R. B. Hough, Lowville, Lewis Co., N. Y.

Lower Silurian fossils from near the Falls of St. Anthony, Minn., for good microscopic material, etc. John Walker, 810 Ave. S., Minneapolis, Minn.

HOME ARTS.

VOL. IV. NEW YORK, FEBRUARY, 1881. No. 2.

Fresh Water Mussels for the Aquarium.

BY A. W. ROBERTS.

IN MOST works on fresh water aquaria, mussels, (bivalve molluscs), are spoken of as being of little use, and devoid of interest. Such has not been my experience, as I have found them to be very useful, very interesting and beautiful objects for the fresh water aquarium.

Fig. 1 (see next page) represents the *Unio radiatus*, one of the most highly colored of this very large genus of molluscs common in our lakes, and slow flowing rivers and streams. The shell of this unio is of a light green color, merging into a yellow. From the " beak " (the highest point of the shell), radiate streaks and dashes of a dark and intensely rich green.

Fig. 2 is the *Anadon fluviatilis*, the most common of all fresh water mussels in New York State. In color, it is a dark brown in the young specimens, and in the matured, almost black, with the shel s more or less decomposed by the action of water which causes an exposure of the pearly structure of the shell as shown in the illustration.

The white foot of the mussel is shown in the figure partly extended from the shell. With this foot it burrows into the sand and pushes itself about from place to place. After having burrowed, it opens its shells and extends its syphonal tubes for the purpose of breathing and feeding. If closely watched, a current of water may be seen passing down and out of the tubes, this current is produced by a fringe of tentacles that surround each tube, each tentacle being furnished with rapidly moving cilia, which cause the water to pass in and out of the syphonal tubes. These tentacles when examined under a microscope are very beautiful objects. In the figure the tubes are shown at the lower end of the mussel.

I have found mussels indispensible

where a tank of water has become charged with a sudden development of minute animal or vegetable life, causing the water to look cloudy. With the assistance of a few mussels the water can be restored

Fig. 1. UNIO RADIATUS.

to its original clearness in a few hours. It is these minute vegetable and animal organisms that constitute the natural food of the mussel. On very many occasions, in the months of July and August particularly, when the temperature of the water in my tanks was rapidly approaching 80°, causing immense and sudden developments of animal and plant life, I

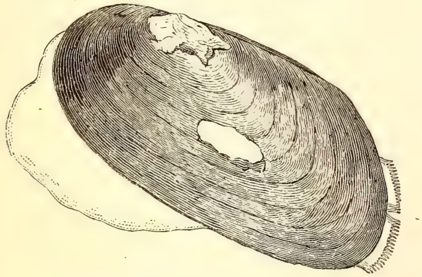

Fig. 2. ANADON FLUVIATILIS.

have used mussels with perfect success. Like the other animals confined in an aquarium, they must be watched, and that very closely, for if one should hide away and die and not be discovered it will be very apt to poison the water beyond recovery. A dead mussel can be known by his gaping shell; still, when doubtful, touch his shell near the syphons with a stick, and if he does not close up quickly, it is best to take him out and examine him carefully.

Thousands of these mussels are taken every year for the valuable pearl material, of which their shells are mainly composed, and which is worked into various articles by workers in pearl both in this country and Europe. Large quantities of these shells are shipped to England to be polished and mounted in gold and silver for ladies portemonnaies, which are again shipped to this country to be sold, they being in great demand by the fair sex, yet, if they were told that they were carrying in their pockets American clam shells, how quickly their admiration would cease.

It is not so many years ago since the inhabitants of New Jersey turned out *en masse* to dig mussels in the streams and ditches, for the pearls they yielded, many of which sold for high prices. I knew of some lumbermen from Maine, who, during their leisure hours, collected pearls from the mussels growing in the small streams and rivers near their camp. Some of these pearls were very beautiful both in shape and colors, being of blue and pink tints, for which they obtained high prices from our leading jewelers.

The rivers of Scotland, Ireland, Wales and Bavaria, abound in these pearl-bearing molluscs, and at the present day many fresh water pearls of value are being worn by the nobility of Europe.

Linnæus discovered by actual experiment that grains of sharp sand introduced between the valves of the shell in such a way that they rested between the body of the animal and the "Mother-of-pearl," or nacre, caused in a short time the deposition of a coating or crust of pearl on the sand grain, which, acting as a nucleus, gathered the shielding matter around it, and so guarded the delicate tissues, of the mollusc from friction and injury. It has also been found that by drilling a small hole through the outer coatings of the shell, and leaving the lining untouched by the boring instrument, that a pearl nodule was formed. This fact has been taken advantage of by the Chinese, who, introduce small images of their 'Josses' into the valves of the pearl oyster, which in course of time coats them with nacre.

Three Amateur Workers—and What They Did—VI.

BY FRED. T. HODGSON.

SEVERAL evenings after Fred had finished the mitre-box, Mr. Carpenter, Mrs. Carpenter, Jessie and the boys were sitting at the tea table, when Mrs. Carpenter asked Fred how he was getting along in the workshop.

"I think I am doing very well, Ma; at least Pa says I am, and you know he would not say so if I was not. I have made a mitre-box, and a work-bench, and two saw-horses, and I think I will soon be able to make you something nice; a flower stand or a cabinet, or some other equally good thing."

"I do not wish you to make anything for me yet, Fred. You must first make something for Jessie and Ellwood, and yourself. I can wait, and it will please me as well to see you make something for your brother and sister, as it will to have you make things for me."

"Oh yes!" said Ellwood, "I want Fred to make me a wagon or a sleigh, the first thing. Can't he, Ma?"

"Why, Ellwood," said Mr. Carpenter, "you know you had a wagon a short time ago. I think you can afford to wait a little while before getting another. Don't you think, Ellwood, that we all ought to give way like your Ma, and, instead of asking Fred to make anything for you or I, go to work and help him to make a little house for your sister Jessie?"

"Never mind me just yet," said Jessie, "I can wait until Ellwood gets his wagon."

"You are too kind, my dear," said her father. "I am sure Ellwood will be pleased to see you have a nice play house finished before he gets his wagon."

"Of course I will," said the boy, "I did not think about Jessie's house, or I wouldn't have mentioned about the wagon. Can't we go in the shop and start making the house to-night, Pa?"

"Yes," said Mr. Carpenter, "we will go in as soon as tea is over, but we cannot do much at it to-night, we can cut the stuff up, however, and make such preliminary arrangements as may be necessary. Before we can finish the house I will be compelled to buy some more tools for you; and now I think of it, I must also purchase a good scroll saw, one that can be driven by foot-power."

"Oh yes, Pa!" cried out Ellwood, "and get a saw with a turning lathe attached, that will be jolly, for then I can turn base ball clubs and other things."

"I don't think it will be wise to get a scroll saw with a lathe attached, Ellwood," said Mr. Carpenter. "All the tools I have purchased so far, are good, and capable of doing any kind of work within their range, and I think it will be better, when I do buy a lathe, to get one that will be in keeping with the tools already purchased. You cannot do any heavy work with those small lathes that are usually attached to saws; they will do small work very well, and many nice things can be made with them, but one of them would not suit us; I will get a good saw—one that will cut thick stuff as well as thin, and then it will answer all our purposes."

By this time tea was over, and the father and his two boys rose from the table and went direct to the workshop. Jessie would have gone too, but it was her usual custom—good girl as she was—to assist her mother and the servant, to put the dining room in order when tea was over. She soon followed her brothers into the shop, however, as she was just as anxious about her prospective play house, as any other little girl would be that was going to get one made.

When Jessie reached the shop, her father asked her how many rooms she would like to have in her play house.

"Well, Pa," she replied, "let me see. I think I would like to have a dining room, a parlor, a kitchen, pantry, and three or four bed rooms, a main hall down stairs, and a nice hall up stairs, and ——"

"Stop, my dear girl! stop!" said Mr. Carpenter, "you will give Fred a year's work if you continue. I think, if you get a play house with four rooms, and two halls in the main part, with a kitchen and pantry attached, it will be quite large enough for you. Don't you think so my pet?"

"Well, Pa, I will be satisfied with the number of rooms you say, but you will make the rooms large, won't you?"

"Yes," said her father, "we will make them a good size. We will have the parlor 18 inches long by 14 inches wide, and the dining room 12 inches by 18 inches, and two bed rooms in the second story the same size as the rooms down stairs. We will make the lower hall ten inches wide, and the upper hall the same width. The length of both halls will be the same as the length of rooms, eighteen inches. Now, if we imagine these lengths and widths to be in feet instead of inches, it would make the house appear to us to be a pretty large one. In fact, I intended that the house shall be built on the scale of one inch to the foot, or in other words, each inch on the play house, in any direction, will represent one foot of a real house—thus: the 18 inches which show the length of the parlor will represent 18 feet, thus showing the room to be 14 by 18 feet. We may consider the house we are about to erect as one-twelfth the actual size of a house whose dimensions are on the ground plan, eighteen feet by thirty-six feet. If you study this matter a little, you will understand why it is that architects and engineers make all their drawings to a scale."

The size of the house having been decided upon, it was determined to commence operations at once, so Fred chose out a number of boards, and under the directions of his father measured off the stuff.

For the sides he took boards ten inches wide, and cut them off 27 inches long. These were intended to stand on their ends, forming a wall 27 inches high by 18 inches wide. He planed and jointed this stuff, and then matched or tongued and groved the central joint with a pair of match planes* his father went out and bought, whilst he was cutting the stuff.

*Fig. 22 shows a pair of match planes in position for work. s s s s shows the several pieces of stuff tongued and groved. The planes are made in pairs, and the irons are nicely adjusted to match each other. They should never be used on stuff thicker than the width of the groving iron. Different thicknesses of stuff require different sizes of planes.

Fred then tried his hand at matching the side boards, and soon found that there was no difficulty in performing this operation. He finished this work and drove the boards together, then put them aside and began to cut up the stuff for the back, top, and two floors. He made the back 40 x 27 inches. This was two inches larger

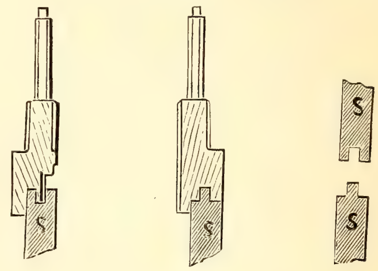

Fig. 22.

than the floors, as it had to be nailed to the sides. The floors were made 18 x 38 inches, and each floor was jointed and matched and cut square on the ends; they were intended to fit inside the sides, but the top, which was left two inches longer than the floors, was intended to nail right on the top of the sides; it was also one inch wider than the floors, because it had to be nailed on to the back.

The back, like the sides, floor and top, was made of narrow stuff jointed and matched. The two sides and two floors were cut to exact lengths as mentioned above, and made exactly eighteen inches wide.

All was now ready to nail together, but as it was getting late, this operation was postponed until another evening.

(To be continued.)

Home-made Telescopes and Microscopes.—XIII.

FORMULÆ FOR A QUARTER INCH AND ONE INCH OBJECTIVE, BY MR. SWIFT.

THE following is a very good formula for a quarter inch objective of eighty-five degrees of aperture, the radii of the curves being given:

1. Back triple combination. Curve of back surface of crown lens, ·525. Contact surface, ·225. Contact surface of lower crown lens, 1·500. Incident surface, ·59.

Working diameter of back crown, ·325. Incident crown working diameter, ·34. These lenses must be worked up to a sharp edge at the above diameters, for the purpose of getting the requisite thickness of the lenses, which, in all optical combinations of this description, is the only method by which it can be readily effected without the necessity of dismounting the lens from the lathe or stick on which it is ground, to gauge its thickness by means of a master-gauge. The finished diameter of these lenses is ·315. Thickness of edge of flint at this diameter, ·080. The middle combination of this objective is composed of two lenses—a double convex crown of ·225, of equal curves, and a plano-concave flint. These, as a matter of course, like the back combination, are cemented together. The working diameter of the crown lens is ·27, when worked to a sharp edge, as before described, the finished diameter being ·26. Thickness of edge of flint, when reduced to the finished diameter, must be ·070. The front glass is a plano-convex crown lens of ·115 radius, which is worked to a half sphere; its diameter, therefore, being equal to double its radius. The combinations of this objective, together with the front lens, are set in their cells against shoulders, which renders the setting or centering of the lenses, after a little practice, a very easy operation. The cell, carrying the front lens for convenience of adjustment, is best screwed to a piece of triblet-drawn tube, which can be made to fit over the cylindrical part to which the back and middle cells are screwed. By this contrivance, the proper point of adjustment on mercury can be readily obtained, by shortening the plain end of the tube fitting until the diffraction rings become equal on both sides of the focus of the objective. The curves of this objective are computed to suit a density of flint 3·9646, crown 2·540. This flint and crown glass is made by Messrs. Chance, of Birmingham, and can be obtained from various dealers,*

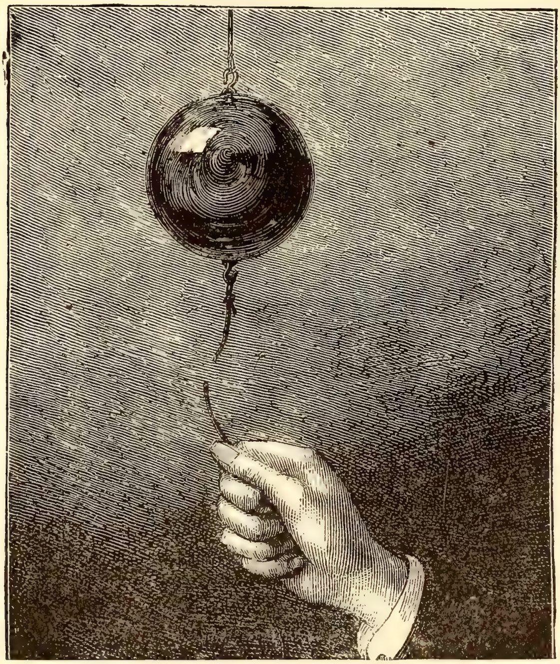
The posterior or back of the one-inch objective is composed of a triple combination. The front or anterior is a plano-convex crown lens and a meniscus flint. The curve of the back surface of the posterior crown lens is ·76. The curve of the next two surfaces is ·525. Contact surface of incident crown, 3·25. Incident or outside surface, 2·5. The back surface of the posterior crown should be worked 8-10ths of an inch in diameter, to insure accuracy of figure. Previous to grinding the contact surface of this lens, the diameter must be reduced to ·615, then worked to a sharp edge, which will give the thickness required for this lens. The working diameter of the incident plate is 9-10ths. This, as matter of course, will be ground to a sharp edge, as before described, for the purpose of getting the required thickness. The best method for an amateur to adopt would be to work the lens on a hard pitch pallet one inch or less in length. The lens is not so liable to tilt in working in the tool as it would be if the ordinary length of stick employed for this purpose were used, This method also applies to the shallow surface of the flint. Diameter of the posterior lenses when finished is 5-10ths; thickness of edge of flint at this diameter will be 1-10th of an inch. Back surface of anterior flint is ·41. Next two, or contact surfaces, ·21. Working diameter of front crown, 4-10ths. Finished diameter ·38. Thickness of anterior flint, at the finished diameter, measuring from back surface to front edge, ·125. Separation between the lenses is 7-10ths. Density of flint, 3·64. Density of crown, 2·540.

* The addresses of the principal dealers in optical goods and materials may be found in the "Microscopist's Annual."

Curious Experiment Illustrating Inertia.

THE experiment which we illustrate in the accompanying engraving, is a very remarkable one, and has the additional recommendation that it is very easily performed. Take a block of wood weighing ten to fifteen pounds, and suspend it by a piece of common cotton twine just as we have shown it. The block shown in the figure is a nicely turned ball, but this is not at all necessary; any kind of a block will do. To fasten the twine, you may use a couple of screw eyes, or even good

stout nails, but see that one piece of twine does not have the advantage of the other, owing to one of them being placed against a sharp edge or corner. If you now give a sudden jerk to the lower cord, you will find that it will break, while the upper cord, which apparently supports not only the force of the jerk, but the weight of the block, is not at all affected. Any person to whom the arrangement is shown before the cord is pulled, upon being asked "Which cord will break?" will almost certainly answer, "The upper one!" And great will be his astonishment when he sees that the block does not fall.



CURIOUS EXPERIMENT IN INERTIA.

The explanation of this singular experiment is very simple; if the jerk be sudden and strong, the under string gives way before there is time to transmit the motion to the ball, and consequently the force to the upper string. The inertia of the ball, therefore, saves the upper string from breaking. If, however, we pull the lower string *slowly*, the upper string will break, because it has to support not only the pull, but the weight of the block of wood. This is merely another illustration of a law which we may see in action around us constantly, and which is frequently taken advantage of to produce very strange results. Thus we would hardly suppose that a man lying flat on his back could bear the blows of a sledge hammer delivered by a strong man on his chest. But if we place a good heavy anvil on his chest, he will be able to bear the weight of the anvil and the blows too, if the latter are struck on the anvil. For the blow, which by its velocity would crush in the chest, is taken up by the anvil and rendered slow and harmless.

So, too, a leaden ball thrown from the hand will, if it strike a window, communicate its motion to the glass and shiver it to fragments. But if it be shot from a gun, so that its velocity is very great, it will not have time to transfer its motion to any more of the glass than just a space equal to its own size; this it will carry away, leaving a round hole.

Dangerous Toys.

POISONOUS confectionery and toilet articles have received a good deal of attention in this country, but thus far we know of no efforts to prevent the sale of poisonous toys.

A plentiful and cheap supply of toys will, it is generally considered, contribute to the happiness of children and the tranquility of their parents, but the recent action of the authorities in Paris suggests that this result may not always be insured. A toy producing the symptoms of lead poisoning is not so conducive to the diversion of children and the peace of their parents, as the Parisian itinerant vendor of these wares would have us believe. A number of boxes, filled with toys, painted in brilliant colors, elastic balls colored and varnished, soldiers in every variety of uniform, have been seized by the French police. It has been proved that the color would easily come off, particularly if the children put the toys to their mouths—a habit which seems inherent in every child's nature. "These playthings," says the *Lancet*, "painted with poisonous colors, had been imported from Furth, in Bavaria, and a committee of the manufacturers of that town has recently held a meeting on this subject. A circular was at once issued to all the toy manufacturers, urging them to use non-poisonous paints, and reminding them that according to the German law, they had exposed themselves to penalties—fines and imprisonment." The *Gesundheit*, of Frankfort, remarks that but for the repressive measures adopted in Paris, the German authorities would still neglect to enforce the German law. This apathy, according to the German papers, is all the more reprehensible, as the Furth manufacturers send their toys all over Germany, and may, therefore, poison the children of the Fatherland as well as the little Parisians—a consideration which, in the Teutonic mind, must greatly increase the gravity of the question. To us the matter is not less serious. It is well known that the majority—in fact, nearly all—of the cheap toys sold in the United States, are imported from Germany, and we regret that it is to the Parisians rather than to the United States authorities that we must attribute the honor of seizing these dangerous playthings. We trust that no time will be lost in following this excellent example, and that a more strict watch will be kept to prevent the importation from abroad of poison for the nursery.

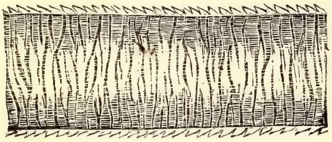
How a Hair Looks Under the Microscope.

EVERYBODY has heard of hairs as seen under the microscope, and this and "the animalcules in water," are generally the first objects that most people desire to see when the opportunity of looking through a microscope first presents itself. The popular ideas as to how a hair looks are very vague, and in many points erroneous, particularly those in regard to all hairs being *tubes*. This error has been repeated time and again in popular books, and yet, as we shall see, it has not a particle of foundation, so far as *human* hairs are concerned.

Nothing puzzles a beginner so much as the getting of a hair fixed under the microscope so that it can be well seen, and if you wish to test the skill of an amateur microscopist ask him to show you a hair. If he is very inexperienced he will lay it on the stage, and will find it impossible to arrange it under the objective. Or, perchance, he will lay it on a glass slide; it is then more easily adjusted, but the probability is that as soon as an attempt is made to look at it, the breath of the observer will blow it away. After this difficulty has been found two or three times, the young microscopist will probably cover the hair with a piece of thin glass. It is now easily managed, and can be very readily brought under the object-glass of the microscope, but the view is misty and very unsatisfactory. Unless he has a teacher, or has learned from books how to do it, this is as far as the beginner is likely to get. We will, therefore, tell our young readers how to manage a hair so that it can be seen clearly and well, and without any bother or trouble.

If you wish to get very good results, place the hair in a small phial of ether or

strong alcohol, and soak it until all grease and dirt have been removed. If you have no time for this, however, as when somebody plucks a hair and asks you to show it, simply wipe it and place it on the slide. If there should be no objection to doing so, cut off a piece of the hair, about half an inch long, and use that. Take a clean slide and place on it a drop of a mixture of equal parts of glycerine, alcohol and water, as described in the YOUNG SCIENTIST for December, 1879. In this drop place the hair; arrange it by means of a needle stuck in a small wooden handle, and when the hair has been thoroughly moistened and covered with the liquid, place a piece of thin glass over it. You can now place



HUMAN HAIR SEEN UNDER THE MICROSCOPE.

it under the microscope, when it will look just as we have shown it in the engraving. Across the body of the hair are seen many lines; these are the edges of the scales with which the hair is covered, and the saw-like notches are the edges of these scales seen in profile.

It will be noticed that along the centre of the hair there is a light streak; it was this which gave rise to the idea that hairs were tubular. It will be found, however, that a solid wire presents the same appearance, so that the light streak is due to the round form of the hair, and not to its being hollow. This is proved more fully by cutting the hair square across, and looking at it endwise. In regard to the best methods of doing this we shall have something to say in a future article.

Cheap Lathes and How to Use Them.—II.

CHOICE OF A LATHE.

WE at first intended to address ourselves wholly to those who were already in possession of a turning lathe, but since the publication of our first article on the subject, we have received so many requests for advice in regard to the purchase of this tool, that we feel obliged to say something in regard to the choice of a lathe.

Lathes can be obtained at almost any price, from $3 up to $1,500. The cheapest lathes are those little things attached to scroll saws. In these lathes, poor as they generally are, a turner who is really expert can make some very pretty and very useful articles. We say *really* expert, because it is not every man that can turn out fine work that is really expert. In many cases the lathe itself does nearly all the work, being self-acting and furnished with all necessary means and appliances. On such a lathe the merest bungler can do good work. But to take a weak, shaky, untrue lathe, and by skilful manipulation to bring forth something presentable, that shows true skill. Many of our readers, no doubt, own such lathes; hereafter we will tell them how to remedy their defects and avoid the errors which these defects are likely to introduce, but in giving advice in regard to the *choice* of a lathe, we would say avoid them. A beginner should, if possible, procure a good tool, for he will need its aid to produce respectable work, and besides he will find difficulties and defects enough in himself without having to worry over those of his lathe.

At prices ranging from $15 to $25 very excellent lathes may now be had. These lathes are all metal; the workmanship is excellent, and the material is of the best. If the lowest of these figures is beyond the reach of the reader, he must content himself with one of those lathes which have only metal heads on wooden "shears" or "bed," as this part is sometimes called. At one time wooden shears were very common, even in the best lathes, and some of the old tools, with mahogany beds, were capable of doing very accurate work. But since the planing machine, and other tools driven by steam power, enable us to work iron almost as easily as wood was formerly worked, wood has been abandoned as a material for lathes except in the very cheapest kinds. Therefore, when only a very cheap lathe is within the reach of the reader, he will probably select one

made largely of wood. There is not much room for choice amongst lathes of this kind.

When the intending purchaser is not confined to the *cheapest* form of lathe, the first question that will arise is as to the size that should be procured. At first sight it would seem that the larger the better—within reasonable limits. For since small objects can be turned on a large lathe, while large objects cannot be turned on a small lathe, it would seem that all the advantage was on the side of the large lathe, and to get two, a large and a small, would be to imitate the man who had two holes made in his barn door—a large one for the old cat and a small one for the little kittens, forgetting that a very small kitten can go through a very large hole.

A lathe that is too small is a constant source of annoyance where the owner desires to do general work. Of course if the lathe is intended for some special department, such as turning the fittings of small optical apparatus, such as microscope objectives, etc., the case is different, but this is not a frequent case.

There are two directions in which the size of a lathe is measured; the first is the diameter of the object which it is capable of turning, and the other is the length of the article which it can take in. Some lathes are made capable of taking in work of very large diameter, while the beds being very short, they are fitted for turning up wheels, pulleys, and such articles, but not for anything that is long. Other lathes are made exactly the reverse of this, being fitted for turning articles of great length but small diameter. The amateur, however, unless he has some special work in view, should select a well-proportioned lathe, and we think that one capable of taking in articles eight to nine inches in diameter, and three feet long, is about as good a size as can be chosen. When we say eight or nine inches in diameter, we mean, of course, over the bed, and not over the rest, for it will scarcely happen that the amateur will have to turn an object nine inches in diameter and three feet long, though he may often have to turn objects three feet long, and others that are nine inches in diameter.

When articles of greater length or diameter are to be turned, it will often happen that the young workman can, by a little contrivance, devise means for performing the work. Thus, in our own practice, we have often managed to build up a temporary bed, on which the tail-stock might be placed, and in this way we have succeeded in turning up simple work of considerable length. And on the other hand, by turning the head-stock round so that the face-plate would hang over the left-hand end of the shears, and by rigging up a temporary support for the tool rest, we have succeeded in turning up articles of considerable diameter on a very moderate-sized lathe.

Of course these make-shifts will not do for intricate work, or for turning metal or heavy pieces of hard wood, but they answer very well for light and simple objects.

Having decided upon the size and price, the next thing to be done is to examine the various lathes in market, so as to select the best that comes within the limits of the points we have mentioned. Each part of the lathe under inspection should be carefully examined, and directions for doing this will be given in our next article.

BOOK NOTICES.

Practical Hints on the Selection and Use of the Microscope: Intended for the Use of Beginners. By John Phin, Editor of the *American Journal of Microscopy* and the *Young Scientist.* Third Edition. Thoroughly Revised and Greatly Enlarged. With Six Full Page Plates and Seventy-six Figures in the Text. Price 75 cents. New York: Industrial Publication Co.

This work has been out of print for some time, as the publishers were unwilling to send the old plates to press without thorough correction. The work of revision has been more extensive than was anticipated, and has occupied considerable time, but the advance sheets of the work are now on our desk, and the complete volume will be accessible to our readers before many days pass by.

The book we leave to other hands for criticism. That it has numerous faults we are fully aware, and we know that these have not been entirely eliminated. Fully one half the book has, however, been entirely rewritten, and the whole has been extended to 240 pages, instead of the 181 of the former edition. The kind reception accorded to the first and second editions leads the author to hope that the present one will not be entirely unacceptable to our young friends who are interested in microscopy.

Nickeling Small Articles.

Many unsuccessful attempts have been made to nickel small articles by boiling, just as pins, hooks and eyes, etc., are silvered or tinned. Dr. Kayser is said to have succeeded in coating metals with an alloy resembling German silver, thus giving them a handsome finish, and making the surface more durable and permanent than that of tin or silver. He first melts together 1 part copper and 5 parts pure tin—preferably the Australian, which has recently come into commerce, almost absolutely pure, yet cheaper than Banca tin. The alloy is granulated as usual, but not too fine, and then mixed with water and tartar, as free from lime as possible, into paste. To each 200 parts of the granulated alloy is added 1 part ignited oxide of nickel, and the articles are laid in it. After boiling a short time they become beautifully silvered. Some fresh oxide of nickel must, of course, be added from time to time. Brass and copper articles can easily be silvered in this manner without previous preparation; those of iron must first be copper plated. By adding some carbonate of nickel to the above bath, or to a common white bath, and boiling, a coating richer in nickel is obtained, and darker, varying in color from that of platinum to a blue black, according to the amount of nickel salt added.

To Render Plaster Casts Water-Proof.

Mr. R. Jacobsen gives the following method for preparing gypsum moulds so that they will permit being washed. A neutral soap of stearic acid and caustic soda is prepared and dissolved in about ten times its weight of hot water. The moulds or objects are either coated with, or immersed in this solution. By this procedure the color of the object is not affected, it is rendered impervious to moisture, and permits the object to be washed, even with lukewarm soap water, since stearate of potassium is only soluble in hot water. Soap water is entirely superfluous for washing gypsum casts; warm water is all that is requisite. Ordinarily, moulds, etc., are cleaned of dust and dirt by means of soap water. This removes the dirt, but leaves, in its place, a film of soap, which most readily collects and retains dust. This same difficulty is presented by gypsum that has been impregnated with a solution of alum and stearine. A coating made with a solution of stearate of alumina in benzole behaves in a similar manner. The gypsum can also be made impermeable to water by saturating it with a solution of oleic acid in benzine; this should be but slightly colored and oxidized. This solution is to be applied to the object when cold, and in such quantity as to completely saturate the gypsum. These objects are not to be cleaned with soap water, since this would take up the oleic acid, but should be wiped with a cloth, moistened with the acid. The first described method gives the best results, and is especially to be recommended in voluminous castings.—*D. Ind. Zeitung, ix*, 82.

Microscopic Lead-Trees.

A writer in the *English Mechanic* says: "To make the above, place some good-sized pieces of gum arabic in a saucer, and then pour in acetate of lead until they are half immersed. In about twelve hours some of them will have a clear drop of thick gum on the top. Put some of this on a slide on which zinc has been filed with a fine file, and instantly place over it a glass cover. If the slide is at once placed under the microscope, the trees may be seen growing, but slides that are intended for the box should be kept under pressure until dry. They will not require cementing or papering, the gum being quite sufficient for the purpose. I discovered this method about ten years since, and find the slides I then made to be in perfect preservation. The finer the zinc particles and the weaker the acetate solution, the finer will be the trees, and *vice versa*."

Patina on Zinc.

Patina is a term applied to the coating which the natural corrosion of the elements produce on metals. A solution of molybdic acid or of molybdate of ammonia in weak *aqua-regia*, or a solution of molybdic acid in an excess of strongly diluted soda lye, furnishes, according to M. de Kletzinsky, a very good bath with which to obtain a patina on objects cast in zinc. The objects are simply immersed in a bath, when they shortly acquire a brownish patina, very agreeable to the sight, and having a characteristic iridescence. The effect here described is due to the formation of a thin film of oxide of molybdenum, which develops the colors of polarization, and which adheres strongly to the zinc.

Crystallized Wood and Paper.

According to Professor Boettger, the simplest method of giving paper and wood surfaces a crystalline coating is as follows: Mix a very concentrated cold solution of salt with dextrine, and lay the thinnest possible coating of the fluid on the surface to be covered, by means of a broad soft brush. After drying, the surface has a beautiful bright mother-of-pearl coating, which, in consequence of the dextrine, adheres firmly to paper and wood. The coating may be

made adhesive to glass by doing it over with an alcoholic shellac solution.

Professor Boettger mentions the following salts as adapted to produce the most beautiful crystalline coating: sulphate of magnesia, acetate of soda, and sulphate of tin. Paper must first be sized, otherwise it will absorb the fluid, and prevent the formation of crystals on its surface. Visiting cards with a mother-of-pearl coating have for some time been in use. Colored glass is well adapted for such a coating, which has a good effect when the light shines through.

Practical Hints.

Mistakes of Letter Writers.—The following are some of the reasons why a letter does not go:

Because you forget to address it.

Because you forget to stamp it.

Because you forget to write the town or State on the envelope.

Because you used a once cancelled stamp.

Because you cut out an envelope stamp and pasted it on your letter.

Because you used a foreign stamp.

Because you wrote the address on the top of the envelope, and it was obliterated by the post office dating, receiving, and canceling stamps.

And because you put your letter in a blank envelope, and sealed it and forwarded it to—the Dead Letter Office, where thousands upon thousands of valuable letters are daily destroyed because the people are either careless or ignorant of the postal laws.

And to the above we would add a few reasons why an answer don't come:

Because you do not sign your name.

Because you sign it so indistinctly it cannot be read.

Because you do not give name of post office.

Because you do not give name of State.

Because you write with a pencil, which is rubbed off and illegible.

Because you use ink so pale and dim it cannot be read.

Because you write so poorly no one can read it.

Because you do not enclase stamp to prepay postage on the answer.—*Saturday Night* (*Cincinnati*).

To Soften Hard Putty.—A correspondent of *The Garden* says: After many trials, and with a variety of differently-shaped tools, with various success, I at last accomplished my end by the simple application of heat. My first experiment was with a soldering iron, when, to my great delight, I found the putty became so soft that the broken glass could be removed by the fingers and the putty be easily scraped away. All that is required is a block of iron about two and a half inches long by one and a half inches square, flat at the bottom, and drawn out to a handle, with a wooden end like a soldering iron. When hot (not red) place this iron against the putty or flat on the broken glass, if any, and pass it slowly round the sides of the square. The heat will so soften the putty that it will come away from the wood without difficulty. Some of it may be so hard as to require a second application of the hot iron.

A New Mode of Treating Burns.—The removal of infiltration of the skin is easily accomplished, according to M. Ungerer, by osmose. He had occasion to prove this lately in having to treat an extensive scald on the hand, which resulted in a large and exceedingly painful swelling without wounds. Cold water treatment for 12 hours did not relieve the swelling in the least, and the pain was almost unbearable when the hand was removed from the water only a few seconds. He, therefore, made a diffusion experiment, dipping the hand in a saturated salt solution, and the success was surprising. Though the salt solution had not the temperature of the ice water, the pain diminished almost immediately, and in four hours blister and pain were both entirely gone. The hand next day differed from the other only by a very slight swelling and redness.

Inlaying.—Inlaid wood is held in place by the tightness and completeness with which the inlaid parts are mortised into the main body or bed of the wood. They are also held in by pins or pegs when the pieces are large and the hold given by the sides of the mortise is insufficient. When thick slices, or masses of ivory or metal, or even thin metal are used, as in Boulle work, the metal should have the help of small pins at intervals. But the chief agent in connecting surfaces of wood to slices of ivory, bone, horn or thin shell is glue, which, when good and properly applied, holds with a degree of strength that is sufficient on almost any requirement.

Moire Metallique.—The following is given as a method of crystallizing tin plate. Heat the plate till the tin begins to melt, and dip it into a solution of 1 part of bichromate of potassa in 3 parts of water, 2 parts of muriatic acid and 1 part of nitric acid. After rinsing well, muriatic acid is poured over the tin plate, and then a solution of 10 parts hyposulphite of soda in 120 parts of water. The crystalline flowers produced hereby display a great variety of colors, according to the time of contact. Rinse well with water, then with alcohol, and lastly lacquer.

Pocket Mucilage.—Boil one pound of the best white glue and strain very clear; boil also four ounces of isinglass, and mix the two together; place them on a water-bath with half a pound of white sugar, and evaporate till the liquid is quite thick, when it is to be poured into moulds, cut, and dried to carry in the pocket. This mucilage immediately dissolves in water, and fastens paper very firmly.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, whe we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

To exchange, fine imported game fowls of the best strain for Fleetwood scroll saw, compound microscope, telescope, magic lantern, shot gun, or offers. E. Alexander, Johnstown, Fulton Co., N. Y. Box 47.

Wanted, scientific books, minerals fossils and Indian relics, in exchange for minerals, fossils Indian relics, shells, etc.; send for lists; correspondence in German and English. A. W. Baily, Box 712, Atlantic City, N. J.

J. T. Bell, Franklin, Pa., has set of ivory chessmen, German flute, six extra keys, value $12, books, etc., to exchange for magic lantern, music box, guns, revolvers, or offers.

Birds eggs and arrow-heads to exchange for fossils and minerals, and birds eggs; send for my list. Clement G. Burns, Salem, Col. Co., Ohio.

Minerals (zeolites, etc.), to exchange for other minerals; state what specimens you have to exchange. H. L. Clapp, 35 West Cottage St., Roxbury, Mass.

Cabinet mineral specimens of Idaho in exchange for books, minerals, curiosities, etc., etc.; send for list and state what you have to exchange. P. Clough, Junction, Lemhe Co., Idaho.

Type, in exchange for curiosities, fossils, etc. Geo. K. Fischer, 729 North 6th St., Philadelphia, Pa.

I have some stamps which I would like to trade for stuffed birds, birds eggs and nests; I am also open to an offer; send for list of stamps. A. G. G., Box 26, Summit, New Jersey.

U. S. and foreign postage and revenue stamps for others; U. S. match and medicine especially; send list or sheet and I will do the same. B M. Hammond, cor. Elm and Live Oak Sts., Dallas, Texas.

Wanted, a hand or self-inking printing press, small size, in exchange for books, magazines, papers, etc. B. D. Howell, High Bridge, Hunterdon, Co., N. J.

Demas lathe sea shells, rubber boots, California woods, YOUNG SCIENTIST and paper shells, for stencil dies, boxing gloves, revolver, foils, book on navigation, and manly arts. A. W. Port, San Diego, Cal.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

Wanted, to correspond with some one living near the ocean beach also some one living near any lead or copper mines. Ewing McLean, Greencastle, Ind.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

I have 2.000 foreign stamps that I would like to exchange for others. F. Cushing, P. O. Box 178, Wattsburg, Erie Co., Pa.

Wanted back numbers of "American Naturalist" and "American Journal of Science and Arts" (Silliman's Journal), for beautiful specimens, named, of American ferns, mounted or unmounted. Box 16, Pine Plains, N. Y.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

Wanted, a household microscope, telescope, large lenses, well-mounted slides for the microscope, books on the microscope or entomology, in exchange for stuffed birds or minerals; describe offers, and state what is wanted in exchange. E. O. Tuttle, Hampden, Mass.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J,

Minerals to exchange for other minerals; state what specimens you have for exchange. Samuel Wynne, Box 54, Phoenixville, Pa.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa,

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Idaho Mineral Specimens, for bound books on science, travels, history, biography, political, masonic, and others that are instructive. J. P. Clough, Junction, Lemhi Co., Idaho.

I have minerals (including fossils and dentrites), to exchange for minerals; also a papyrograph outfit, without press (worth $25), for offers. W. H. Eastman, Hyde Park, Mass.

Klose's celebrated "School for the Clarionet," new, $3; will exchange for telescope, microscope, piccolo, books, or offers. Rush Holbrook, Wonewoe, Juneau Co., Wis.

One or two handsomely mounted red deer heads, attractive ornaments for any dining-room or hall, for microscope, telescope, sporting implements, camping outfit, scientific books, or offers. R. B. Hough, Lowville, Lewis Co., N. Y.

Lower Silurian fossils from near the Falls of St. Anthony, Minn., for good microscopic material, etc. John Walker, 810 Ave. S., Minneapolis, Minn.

The Young Scientist

SCIENCE IS KNOWLEDGE. KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

Vol. IV. NEW YORK, MARCH, 1881. No. 3.

Great Workmen and Their Tools.

WE called attention in the first number of the Young Scientist, to what might be done by "makeshift" apparatus, and during the past few months, under the title of "Science in Common Things," we have tried to show how very important truths might be illustrated by very simple appliances. The illustrations of these articles were first published in the French journal, *La Nature*, and they have been copied into several periodicals. But though we have borrowed the *illustrations*, the articles which accompany them in the Young Scientist are all original, and have been written specially with a view to the tastes and wants of our own readers.

But while advocating so strongly the use of very simple apparatus for the purpose of *illustrating* scientific truth, we must caution our readers against applying the same rule when they want to find out any of the great truths of nature. Great men, entering for the first time upon some special line of investigation, have made the most wonderful discoveries by means of the most simple tools. Thus, Ferguson, by means of a thread and a few small beads, was enabled to make a map of the stars; and his wooden clock, constructed out of coarse materials by means of a penknife, was certainly a wonderful performance. But his map was, after all, a poor affair compared with those that are now in use; and his wooden clock would hardly have served to run railway trains by. On the other hand, Newton, by means of a prism, a lens, and a dark room, unfolded the composition of light and the origin of color; Black's famous discovery of latent heat was made with a few thermometers and a pan of water; and Watt's first model of the condensing steam-engine was made out of an old anatomist's syringe, used for injecting bodies previous to dissection. But these are not safe examples for imitation. New-

ton, Black, and Watt performed wonders by very simple means; but it took a Newton, a Black and a Watt to do it. The truth is, that, when we get beyond the first elementary experiments, we cannot rely upon any but the most perfectly constructed instruments. Modern chemical analysis demands the use of balances, weights, and measures that cannot be extemporized even by ingenious mechanics; the spectroscope, the microscope, and the telescope of modern times are so perfect and have been so generally applied, that a person working with such a telescope as that with which Galileo discovered the moons of Jupiter, would stand but a poor chance of gleaning anything worth notice. The journals devoted to popular scientific articles are full of articles telling how this, that, and the other great man accomplished wonders with very simple tools. Thus, there is an anecdote told of the famous Dr. Wollaston, to the effect that a foreign *savant* having called upon him and expressed a desire to see his laboratory, in which science had been enriched by so many important discoveries, the doctor took him into a little studio, and, pointing to an old tea-tray on the table, containing a few watch-glasses, test-papers, a small balance, and a blowpipe, said, "There is all the laboratory I have." It is not at all improbable that the story is true; but, at the same time, we know well enough that Wollaston's laboratories were not only extensive, but filled with large and costly apparatus. His antipathy to display, and his love of privacy, no doubt led him to use the above subterfuge in order to avoid the rudeness of a positive refusal.

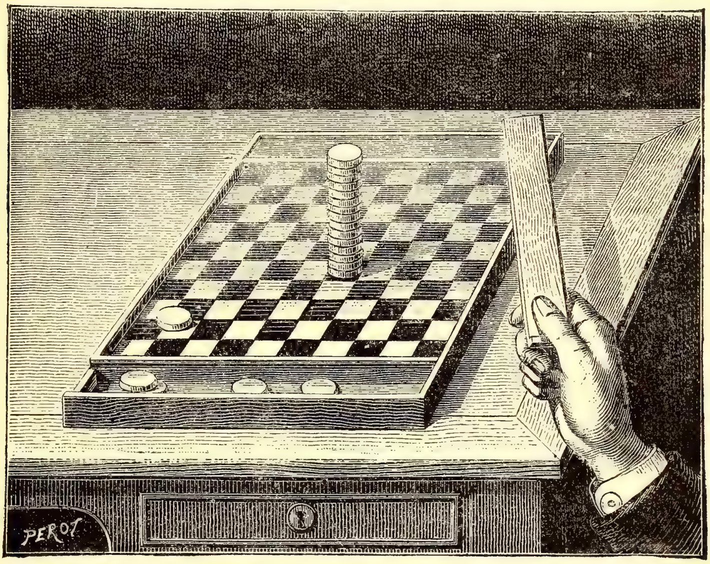
As an offset to this story, we may be allowed to relate two other anecdotes, both quite as well authenticated as the one we have just related. During his investigations into the properties of platinum, he tried furnace after furnace, in the hope of finding one that would produce veritable fusion in the metal. To such an extent did these and kindred pieces of apparatus accumulate, that the room in which the work was done soon became literally filled, and the few visitors that were admitted had to thread a very intricate path which meandered between the huge piles standing on either side. The story runs, that one gentleman, having laid down his hat in one of the bypaths leading from the main avenue, was never afterwards able to find his way back to it, and so lost it.

The second story is as follows: A gentleman, having on one occasion failed to make himself heard by knocking in the outer vestibule, boldly entered the sanctum, where wonder after wonder met his eye. One furnace in particular attracted his attention; and, while he was earnestly gazing at it, Wollaston approached. The philosopher was in a towering passion at having his privacy so rudely broken in upon; so, tapping the intruder upon the shoulder, he asked him if he had taken a good look at the furnace upon which his attention was riveted; "For," said Wollaston, "it is the last look you shall ever take at it," and he unceremoniously turned him out of doors. The truth is, that many of Wollaston's researches were entirely beyond the reach of such a laboratory as could be placed on a tea-tray; and we strongly suspect that the story first related had its origin in the fact that Wollaston was very fond of working upon minute quantities. In Davy's "Chemical Philosophy" will be found engravings of a set of microscopic apparatus, much of which was devised by Wollaston, and very successfully used by him. Faraday, in his "Chemical Manipulation," gives us the following anecdote illustrative of this: There existed in the British Museum a small fragment of a black stone, the source and history of which were unknown. It was unique—no other specimen being known to exist—and Mr. Hatchett, working with a quantity which weighed not more than two hundred grains, was enabled to prove the existence of a new metal, which he named Columbium. Ekeberg afterwards discovered what he supposed to be a new metal, which he named Tantalium; but Dr. Wollaston, having examined it and compared it with Hatchett's account of Columbium, suspected the identity of the two, and was able to prove this identity though he had not more than five grains of the stone

from the British Museum to work upon! But these facts are not inconsistent with the other fact that Wollaston owned and used large quantities of very powerful apparatus. The great point in Wollaston's methods, and that which the student ought to try to imitate, is the proper adaptation of means to ends.

Science of Common Things—Inertia.

NOTHING serves so well to explain any great law as numerous illustrations of it under varying conditions. We therefore give our readers another experiment, which illustrates the same principle as that involved in the experiment with the wooden ball, detailed in our last number. We have here a pile of draughts, and the problem is to knock out one of the lower ones without disturbing the rest of the pile. It is easily done by striking one of the draughts a sharp blow with some thin strip of wood, ivory, or metal. A table knife answers very well—the stroke being given with the back and not with the edge. The special point in regard to which care is to be exercised, is that the stroke be quick and level. If we merely push one of the draughts, the pile will topple over. If the stroke should be at all upward, the upper draughts will be raised and knocked about. The experiment may be varied by placing a card on the tip of the finger and a quarter dollar on the card. A smart blow on the edge of the card will drive it from beneath the coin, and leave the latter poised on the end of the finger.



EXPERIMENT ON INERTIA.

A Strategic Wasp.

NOT long since, while reading beneath the shade of a fig tree, our attention was attracted by a peculiar loud and shrill buzzing sound, as of some one of the bee family in distress. Looking in the direction of the noise, we observed quite close to us a dirtdauber, or builder, one of the species of wasps so well known for the cylindrical cases of mud it builds under eaves and on sheltered walls, which it stuffs full of certain worms and spiders for its young. This wasp had half of its body and head down the hole of the equally well-known doodlebug, a worm which children pull out of their holes by teasing them with a straw until they grasp it with their strong nippers, and

hold on until they are thrown out. It was evident, at a glance, that the wasp had gone down the hole of the doodlebug, and that the doodlebug soon had him in his strong grip at great disadvantage, and where the wings of the wasp were of no advantage to him except to make a noise, which might alarm his adversary. The contest lasted full two minutes, when finally the dirtdauber came out with a jerk. He flew but a few inches from the hole, lit upon the ground, rubbed his head, and fairly danced with pain.

In a few moments he recovered from the effects of his wounds, and began making short circles over the hole, evidently reconnoitering and laying his plans. Presently, lighting at the mouth of the hole, he tried the earth all about the entrance with the skill of an engineer, and, selecting that which was driest, he began to scratch like a dog with his fore feet, throwing the dust rapidly backward into the hole. We watched with intense interest, and could not but admire his pluck and determination, for we imagined this throwing of dust on his adversary's head was only to provoke him to a fresh fight. Every now and then he would stop and take a cautious peep down the hole to observe the effect of his operations. We expected every moment to see him descend and make another attack, but it soon became manifest that such was not his intention, and it gradually dawned upon us that he had a strategic mode of attack based upon the soundest principles of philosophy, reason, and a thorough knowledge of his adversary, and of the means he was using to render his resistance futile and make him an easy captive.

By throwing fine dust into the hole the doodlebug would soon be smothered, as it was necessary that he should have free air, unless he climbed upward, as he would do. Whenever the worm worked upward to get his head above, the fine dust fell behind him, and thus slowly closed up his hole, until, blinded with dust, he poked his head out at the top. This was the point aimed at, and the moment he showed his head above, the wasp pounced upon him, seized him by the neck, drew him up, gathered him in his arms, and flew off in triumph, though the worm was much the largest of the two. Struck with amazement at the sagacity, science, skill and engineering ability of the dirtdauber, we carefully sounded the hole, and found that in the course of five minutes this reasoning insect had filled in five inches of dust, and put his formidable adversary completely at his mercy.

The most skilful engineers could not have thrown up earthworks with a profounder calculation than this natural engineer.—*New Orleans Co-operative News.*

A Fine Cabinet for Nothing.

BY C. LE R. WHEELER.

MANY persons who are interested in Natural History are deterred from attempting to make a collection of specimens to illustrate and help forward their studies, for the reason that they deem it too expensive. My purpose in writing this article is to prove that a genuine interest, a resolute will, and untiring labor, will secure for any person a fine collection to illustrate at least some of the branches of Natural History at a very slight expense; and in some cases, my own for example, at *no expense whatever.*

In the summer of 1876 I returned from the West, bringing with me about seventy-five specimens of minerals. One of the first things that I noticed, upon coming to this place, was a beautiful piece of iron quartz lying in a minister's study. Upon inquiry, I found that it came from a quarry near by. I visited this quarry and others in the vicinity, and found large quantities of rose, greasy, smoky, and white quartz, orthoclase and graphic granite, and many interesting forms of gneiss, granite, and syenite. I began collecting and exchanging at once. One of my first exchanges was with the late Rev. E. Seymour, of New York. I next arranged to send several tons of minerals and rocks to the large Natural History establishment of Prof. H. A. Ward, of Rochester, N. Y. In exchange, I received all that I had expended in cash, and mostly the entire academic set of minerals described in Prof. Ward's catalogue, and I have nearly all of his fine set of rocks

yet to come. Then a sample copy of the Young Scientist reached me, offering an exchange advertisement free to all subscribers. I was satisfied that the tasteful little monthly was well worth the subscription price, and at once subscribed and sent in an advertisement. I soon began to receive letters from all parts of the world offering exchanges, and then found occupation for my leisure hours in packing up specimens and taking care of the packages that came to me by mail, express, and freight from a dozen different States and Territories. The result of this little advertisement has been to add *over two hundred* beautiful minerals, fossils, shells, Indian relics, and coins to my collection. In addition to this, several correspondents, who had more money than duplicates, asked me to sell them minerals; and upon comparing what I have expended for postage, freight, and all other expenses with what I have received in cash, I find that my receipts for minerals sold, have been a trifle more than enough to cover the entire expenses that I have incurred—thus actually giving me "a fine cabinet for nothing."

Three Amateur Workers—and What They Did—VII.

BY FRED. T. HODGSON.

JESSIE watched the erection of dolly's house with great delight, and, it being near completion, she was planning how to furnish it.

"Don't you think, Mamma," she said, one evening, when her and her mother were alone, "I can begin now to make the things for my house? I want to have it just lovely, you know, and it will take lots of time."

"Yes, my dear; I have been expecting you to ask to begin before this. I am glad my little girl has been so patient, and to reward you, Jessie, we will begin to-night."

Jessie was delighted, and ran off to the barn to communicate the good news to Fred and Ellwood.

They did not receive the news with as much enthusiasm as she thought it deserved, they were so engrosed with their own undertakings. So she soon returned.

"Mamma, Fred is going to make some lovely little cornices, with the scroll saw Papa bought, and don't you think we ought to make the curtains first, so that we can put them right up when the cornices are finished?"

"No, Jessie," said Mrs. Carpenter; "I think we will make and lay the carpets first in all the rooms. And then the next thing to do will be to upholster the furniture, which, you know, your Papa and Fred are going to make; it will be ready by that time."

"Yes, Mamma," said Jessie; "I want to furnish it just the same as if it was a big house for real live people to live in."

"Well, then, run out to the barn, and ask Fred to give you the exact measurement of each of the floors."

While Jessie was gone, Mrs. Carpenter brought out sundry bundles and parcels from what Jessie called the pieces drawer, and selecting some pieces of bright-colored plush and carpet, put the rest back, and awaited Jessie's return.

"Here, Mamma," said Jessie, coming into the room with a piece of paper in her hand, "Fred measured the parlor, and Ellwood measured the other rooms, and Papa says they are all right."

"Now, Jessie," said Mrs. Carpenter, "we will make the carpets for the chambers first, out of these small pieces of carpet, and reserve the larger pieces for the other rooms. These pieces are not very large, but if they are sewed together nicely they will answer the purpose very well. Now we will lay them out on the table, and arrange them so that a large cluster of flowers will come as near to the centre as possible. Sew those two pieces together, and I will sew the other two; try and match the pattern nicely and the seam will hardly be noticed, and then we will have one long seam down the centre, and when that is done we will measure and cut it the right size."

"Jessie," said Mrs. Carpenter, as they sewed and chatted together, "In what color shall we upholster the furniture?"

"Well, Mamma, I think red or pink would be nice, don't you?"

"Yes, I think a pale shade of pink

would be very pretty; but as one room is to be used for dolly's servant, it must have something not quite so delicate, and red would be too flaring. We must have all things to harmonize to make our undertaking successful as a work of art and good taste. The selecting of colors and combining them gracefully together is a work of art in itself. Can't you suggest some other color beside red or pink that would combine well with the drab ground of your carpet?"

Jessie could think of no other color, so Mrs. Carpenter proposed crimson or wine color."

"Oh, I think crimson would be lovely," said Jessie.

"Well, then, we will use crimson, and after we have made all the carpets, we will upholster the furniture for this room first," responded Mrs. Carpenter.

Mr. Carpenter. Fred, and Ellwood coming in just then, put a stop to more sewing, as they all agreed to stop at the same time.

After the boys had told their mamma and Jessie how much work they had accomplished, with many expressions about squaring, gauging, beveling and dovetailing, which Mrs. Carpenter or Jessie did not pretend to understand, Jessie produced her carpet; it was pronounced by all to be the very ideal of a carpet. Jessie made some inquiries about the cornices that Fred was going to make for her, and then retired to dream of dolls' houses, carpets, and crimson furniture.

On the following night the two boys, aided by their father, and closely watched by Jessie, began to put the house together, which was found, after all, to be not very much of a job. The sides, floors, and back were all nailed in position, but, indeed, at this stage, the structure had but a slight resemblance to a house.

The next thing to be done was to put a roof on, and to accomplish this a bevel was necessary; but, as usual, Mr. Carpenter had provided for this emergency by purchasing one the day previous. Fig. 23 shows what it is like. The slot in the blade is to permit of the blade to be lengthened or shortened at will. When adjusted to any required bevel, the thumb screw can be turned tight, which will hold the blade where placed until the work is done.

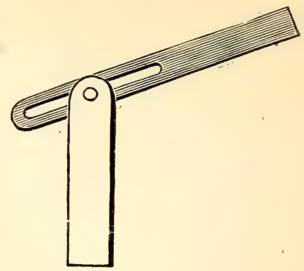


Fig. 23.

Fig. 24 shows a "try-square," two of which Mr. Carpenter bought when he

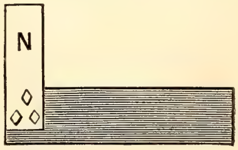

Fig. 24.

purchased the bevel. One had a blade six inches long, and the other ten. The stock, N, is made of rosewood or some other equally hard substance. There will be ample opportunity yet to show the uses of these tools and many others.

(To be continued.)

Management of the Aquarium.

FROGS, TOADS, NEWTS, ETC.

FROGS, toads, newts and salamanders differ entirely in their habits from the turtles, in their being at no period of their existence aquatic, and at other times semi-aquatic, or living part of the time on land and part in water. I can select no better account of the changes they undergo than that given by Professor Quatrefages:

"The development of frogs presents another curious phenomenon; it is this: The young of the animal, after it has left the egg, and before it has become a larva, is still in a semi-embryonic condition. At this period the digestive tube and its appendages are exceedingly rudimentary. The greater portion of the body is filled with a large mass of yolk or vitellus, en-

closed by the skin, which has been formed for some time; and it is at the expense of this alimentary matter that development proceeds. The external characters are in keeping with the imperfect condition of the animal at this period. The head is large, and appears to be divided in two on the under surface, each half being prolonged as a sort of process by which the animal attaches itself to surrounding objects; as yet there are no traces of either eyes, nostrils, respiratory or auditory organs; and the belly, of an oblong form, is continued posteriorly as a short tail, bordered with a riband-like membrane. About the fourth day after birth, the head, which is now as long as the body, has somewhat the appearance of a thimble; the mouth is provided with a pair of soft lips; the nostrils, eyes, and auditory apparatus have made their appearance; the head is separated by a deep groove from the belly, which has assumed a spherical form, and from which spring a pair of opercula, clothed with little branching gills. And the tail has grown so much that it is now quite as large as the body. The mouth is very soon armed with a horny beak, capable of dividing the vegetable food. The intestine, which is now very large, becomes more fully formed, and assumes a spiral arrangement. The tail is elongated and widened, and the little creature is then called a *tadpole*. At this period, one of those alterations occurs which are so intimately associated with the ideas we are endeavoring to convey, that we must not pass them by in silence. Our larva first breathed by its skin alone, and afterwards by a pair of little branching gills attached to the opercula. About the seventh or eighth day the opercula are gradually soldered to the abdomen, and the gills fade away and disappear. At the same time a set of new and more complex branchia are developed in the chambers situate on either side of the neck. The new gills are arranged in tufts attached to a solid framework of four cartilaginous arches, and are about one hundred and twelve in number for each side of the body. Before the tadpole can become a frog, it must do away with these second gills and replace them by lungs; and at the necessary time a set of changes takes place analogous to those we have described. The vascular tufts are atrophied, and the lungs, which till now were solid and rudimentary, open up and increase in size. The circulatory organs are correspondingly modified. The calibre of the large bronchial organs is diminished, and the pulmonary trunks increase in number and diameter. Later on the solid parts of the branchial apparatus disappear also, the bones and cartilages being gradually absorbed. Eventually the alteration is fully accomplished, and there remains not the slightest trace of the former branchial apparatus. In this instance, not only has there been transformation and substitution, but an actual metamorphosis has occurred; for the respiration, which was aquatic before, has become atmospheric, and, strictly speaking, the animal from having been a fish has been converted into a batrachian. If we examine any particular apparatus, we shall find it presenting many curious phenomena in the course of its development. We shall find that as the herbivorous habits give place to carnivorous ones, the digestive apparatus undergoes a change adapting it to the new form of diet. The mouth increases in size and gape; the little beak organs, or, more correctly, the horny lips, are replaced by teeth. The tadpole at first exhibits no trace of either external or internal limbs. It swims about like a fish by the action of its tail, which is an extensive organ, longer and wider than the body, supported by a prolongation of the vertebral column, moved by powerful muscles, and supplied with large blood-vessels and numerous nervous branches. Beneath the skin and muscles of the anterior and posterior regions of the body, two little projections appear at a certain period. These are the limbs, and are at first attached to the adjacent structures by the nerves and blood-vessels which are supplied to them. These projections increase in size, their appendages appear in due course, and eventually the hip and shoulder bones are developed. As soon as these locomotive organs enter upon the discharge of their functions, the tail begins to disappear. Its skin, mus-

cles, nerves, bones, and blood-vessels atrophy, and vanish from our sight. They have not faded away; they have not simply fallen off; they have not been cast off by a species of moulting, as in the case of insect larvæ. They have been got rid of by none of these methods; their substance has been reabsorbed, atom by atom, and hence, although it has ceased to exist, it is not the less alive on that account.

We see, then, that frogs undergo complete metamorphosis, not only in regard to their entire organism, but as to each set of apparatus, with the exception of the nervous system."

Frogs generally spawn about the middle of April, at which time they become very musical.

The ova or eggs of frogs consist of small round opaque bodies, enclosed in a jelly-like substance. This jelly-like substance is for the purpose of protecting the egg from its natural enemies as well as to afford support during incubation. The egg or embryo, consisting of a small globular body, darker on one side than the other, begins to show development within twenty-four hours, the black globes lengthen out, and in forty-eight hours the head and tail are well defined; the fin around the tail now appears, and from each side of the neck the lungs or branchiæ begin to start. In about two weeks' time after the eggs were deposited, the "tads" having absorbed a large portion of the jelly-like coating, break through, and become free. Their lungs now attain their full development, but in course of time disappear, being drawn into a cavity, where they are covered by a fold of the skin resembling the gill cover of a fish. The tadpole now grows very rapidly, feeding constantly on confervæ and decaying vegetable matter.

In the course of a few weeks small projections begin to appear towards the fore and back part of the body; these are the legs just beginning to develope, and, as they grow larger each day, the "tad" begins to learn the use of them, frequenting very shallow water, and rising constantly to the surface to breathe, for by this time the gill covers have closed up, and in place of them he now has perfect lungs and breathes free air through his nostrils. He is still in full possession of his broad fleshy tail, which seems to be greatly in his way, and is all that is left to remind one of his former tadpole condition; but in course of time this is gradually absorbed, till nothing is left of it but just the tip end. He now seeks the shore, and beeomes carnivorous.

The tadpole having become a frog is "small but pleasing to the eye," and is an excellent subject for an aquarium. Frogs raised in an aquarium are always to be preferred, as they are more domesticated, will feed from the hand, and are less liable to wander away. When domesticated, they are very partial to "croton bugs" and roaches, but will not take dead food, though I once had a very large frog which fed on raw beef, but the pieces of beef had to be kept in motion so as to cause him to think they were possessed of life.

Iron Floating on Water.

WE have all heard of the wonderful miracle, by which the Prophet Elisha caused the iron head of an axe to float on the water of the river Jordan. And the floating of iron ships is something with which we are all familiar, either from having heard of it, or from having seen it. A tin or iron cup or basin will readily float, provided it displaces an amount of water greater in weight than the weight of the metal in the vessel. But even a solid rod of iron may be made to float provided it is small enough. Take a fine needle, wipe it with an oily rag, but do not leave any visible trace of oil on it, and then lay it gently on the surface of water in a basin; it will float, and continue to float for some little time. The cause of this is the fact that a quantity of air adheres to the needle sufficient to buoy it up. Moreover, as the cohesion between the particles of water is considerable, and as water has no attraction for a perfectly dry piece of steel, the cohesion of the water is greater than the weight of the metal; and so the latter is supported.

In the same way insects are enabled to walk upon the water. The hairs on the

ends of their feet enclose an amount of air which enables them to float. As each foot is put down it forms a sort of cup-like depression in the water, and the

INSECT WALKING ON WATER.

liquid thus displaced is sufficient to float the insect.

Our young readers will have no difficulty in making the iron wire or needle float on a basin of water, and the experiment is a most astonishing one to those who see it for the first time.

Webb's Celestial Objects for Common Telescopes.

OUR readers will be glad to learn that the new edition of this work, which has been so long out of print, is nearly ready for delivery. The author has revised it with great care, and has added very considerably to the amount of matter which it formerly contained.

Any comments at our hands on this well-known book are unnecessary. It is just the manual for every amateur astronomer, whether he owns a telescope or not. To those who possess a telescope, or who intend to purchase one, the book is simply indispensable. So fully are we impressed with the value of this book, that we have arranged for a special edition, and are thus enabled to offer it at a considerably lower price than it would otherwise command.

We have the advance sheets now before us, and expect the complete work in a few days. The price will be $3, for which sum the book will be sent to any address in the United States or Canada.

New Copying Process.

Mr. Adler has communicated to the Photographic Society of Vienna a new copying process, based upon the use of the glue glycerin pad, which is employed in the hectograph. For the purpose of the new process, however, the pad must contain more glue. The writing or drawing is made upon paper with a concentrated solution of alum, to which a few drops of aniline ink are added, to make the letters or figures visible on the paper. Before transferring this to the pad, the latter is wiped with a damp sponge, and the moisture is allowed to remain a few minutes to make the surface sufficiently absorbent. The paper is now placed on the pad, written side down, and, after a few minutes, again removed, when the writing or drawing will be transferred to the pad. By means of a rubber roller a small amount of printer's ink is now applied to the surface; the ink will adhere only to the lines made by the alum solution. A slightly damp sheet of paper is now placed upon it, and, by gentle rubbing, the writing transferred to the latter. It is necessary to ink the pad each time, but a large number of impressions may be taken, and the prints have the advantage of being permanent and black.—*Pharm. Centralh.*, No. 49.

Preparation of Bone for Turning.

Leg or marrow bones are best: get them and saw off both knuckle ends or joints; with a hooked wire draw the marrow out, put them on the fire in a boiler or saucepan, with some water, and subject them to a simmering heat, which is far better than galloping them out of the pot. After two hours stewing, put by in the liquor until cold, then take them out, dry well in sawdust, and transfer to some powdered quicklime. In a few days they will be fit for use, and may be cut up into rings or strips.* Keep them in the lime until wanted; thus you will have bone equal in appearance to best ivory.

Horse bones are best; ox, sheep, and other animals do for smaller work, but generally I go to the shops that dress cow-heel or neats-feet, and tripe, and get the finest bones for general purposes.—*English Mechanic.*

The Relative Cost of Motive Power.

M. Bissinger, M. E., at Carlsruhe, Germany, gives the following results as obtained in his examinations of the several motors in regard to the relative cost per horse for each hour. It will be observed that the examination pertained principally to small motors. The relative cost per effective horse-power per hour is as follows:

100-horse power steam engine	7.6
2-horse power steam engine	44.3
2-horse power Lehmann's caloric engine	26.5
2-horse power Hock's motor	40.0
2-horse power Otto gas engine	26.4
2-horse power Otto Lang gas engine	26.4
2-horse power Schmidt's hydraulic motor, supplied with water from the city water works	95.00
2-horse power obtained by horses and a gin	45.00
2-horse power obtained by manual labor	200.00

Otto's gas motor and Lehmann's caloric engine are the cheapest of the small motors, but are, nevertheless, four times as expensive as the 100-horse power steam engine.

A Monocular Muse.

BY MARY H. WHEELER.

A Rotifer, deep in an eddy-swept pool,
By the leaf-shaded shore of a rivulet cool,

Contentedly lived in her own minute style,
Invisible, voiceless, but active the while.

And starlight and moonlight, and sunshine and storm,
Lent their varying hues to her transparent form,

And the o'erhanging branches dropped green shadows down
On the flickering sands of the water bed brown.

The minnows above her oft swam to and fro,
And naviculæ sailed o'er the pebbles below,

For the Spring time had come with its warmth and its light,
And the cells of the desmids were verdant and bright-

Closterium segments divided anew,
And the horns of the fair scenedesmus grew,

And the rayed rhizopoda clung lightly between
The filaments of the spirogyra green—

For the season had sent her primordial thrill
Through all protoplasm and chlorophyll.

And the Rotifer, glad in her limpid retreat,
Wheeled through the fair water on cilia fleet.

But a Student, whose nerve cells and brain matter gray
Were attuned to the touch of the sun's vernal ray,

Came, wandering over the vivified sod,
To explore this fair pool with his bottle and rod

And he gathered spores, larvæ, and desmids a few
Some diatoms fresh, and the Rotifer too.

Transferred to the slide of a microscope stage,
And held by a cover-glass close in her cage,

Did the Rotifer sigh for her home in the pool,
And for freedom to roam through its water ways cool?

In the close compressed water and unchanging glare,
Did she long for green shadows and free-flowing air?

Oh, no, she exhibited no such emotion,
But by wheeling and turning soon gave us a notion

She was rather enjoying the new situation,
Though too busy to rest from her old occupation.

And we said it was better this short life to yield
To the great cause of science, in microscope field,

Than to live its few days out unseen and unknown
In ever so pleasant a pool of her own.

Giving this as the fruit of our deep cogitations
The Student we left to his long lucubrations.

Pittsfield, N. H., March, 1881.

A New Liquid Glue.

A solution of 1 part of sugar in 3 parts of water, when appled to paper, gives to the latter neither lustre nor binding properties; but if to the solution be added ¼ part of slaked lime (calcium hydrate), and the mixture, after heating to 145° to 165° F., be macerated for a few days with frequent agitation, most of the lime will dissolve, and the syrupy solution possesses both adhesive and glazing properties. If to 12 or 15 parts of this solution be further added 3 parts of lime, in small fragments, the latter will rapidly dissolve on warming, and, on cooling, will remain liquid, without losing its adhesiveness. According to the quantity of saccharate of lime present, the consistence of the liquid glue will vary; but, in all cases, it will have a strong adhesive power. This liquid glue may be used for a variety of purposes, but must not be employed in presence of coloring matters, which are decomposed by lime, such as Prussian blue, zinc-green, etc.—*Polytech. Notizblatt.*

Dying Horsehair.

Horsehair, from its strength and other characters, is often very useful in amateur work. Black and reddish-brown hairs are easily procured, but where other colors are needed we must procure nice white hair and dye it. This is done as follows: Brown—The hair must first be thoroughly cleansed by placing it in a soap bath, heated to 133°, for twenty-four hours, and moving it about frequently. It must then be allowed to lie for twelve hours in a dye bath, prepared from a decoction of logwood with lime-water at 122°, and then be rinsed and dried. Blue, inclining to violet—The hair must first be dyed brown, as just given, and then passed through water, to which a little of a solution of ten and a half ounces of tin in thirty-five and a quarter ounces of hydrochloric acid has been added, and then washed as in the previous case. Blue—The hair must be prepared in a solution of two parts of alum and one part tartar, wrung out, and passed into an indigo bath, prepared with fuming sulphuric acid, and then rinsed and dried. Red—The hair must be prepared by placing it for half an hour in a tin salt bath, prepared like that for violet blue; after wringing it out it must be dyed with Brazil wood, to which some alum has been added, by allowing it to remain in the dye-bath for twenty-four hours, and then rinsing and drying.

— Repeated applications to copper or brass of alternate washings of dilute acetic acid and exposure to the fumes of ammonia will give a very antique-looking green bronze.

Practical Hints.

Cleaning Ivory and Marble.—The *English Mechanic* gives the following recipes: Polished marble or alabaster, when soiled, may be cleaned with a weak lye of potash and soft soap. Muriatic acid is the best thing for removing iron stains; it should be applied with a rag, but if used too freely or too strong will make the surface rough. The following is the best recipe for removing ordinary stains from ivory or marble: Dust-lime is mixed with the strongest soap-lye pretty thick, and instantly, with a painter's brush, laid on the whole of the marble. In two months' time wash it off perfectly clean, then have ready a fine, thick lather of soap (soft) boiled in soft water; dip a brush in it, and scour the marble, not with powder, as in common cleaning. This will, by very good rubbing, give a beautiful polish. Clear off the soap, and finish with a smooth, hard brush till the end be effected.

To Polish Aluminium.—M. Mouray recommends the use of an emulsion of equal parts of rum and olive oil, made by shaking these liquids together in a bottle. When the burnishing stone is used, the peculiar black streaks first appearing should not cause vexation, since they do not injure the metal in the least, and may be removed with a woolen rag. The objects in question may also be brightened in potash-lye, in which case, however, care must be taken not to make use of too strong a lye. For cleaning purposes benzole has been found best. Objects of aluminium can be electroplated without the least difficulty, and Mouray succeeded in imparting to them a bright white lustre in passing them successively through a weak bath of hydrofluoric acid and aqua fortis. The effect thus obtained is said to be quite surprising.

To Remove Nitrate of Silver Stains.—Dr. Kraetzer, of Leipzig, proposes, as a substitute for potassium cyanide in removing stains made by nitrate of silver, the following: Ammonium chloride, 10 grams; Corrosive sublimate, 10 grams; Distilled water, 100 grams. Preserve in a glass-stoppered bottle. He says that with this solution the black stains may be removed from linen, cotton, and woolen goods without injury of the fabric. It will also remove these stains from the skin, but although it is less poisonous than the cyanide, it is a corrosive poison.

Fire-Proof Cement.—No cement that contains organic matter, such as oil, glue, etc., can resist a low, red heat. For a cement that will resist any heat above that of melted lead we must use materials that are of an entirely mineral character. Finely-powdered asbestos, made into a paste with silicate of soda, forms an excellent fire-proof cement. It hardens quickly, makes joints that are steam and gas-tight, and stands any ordinary heat.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

For exchange, pocket lantern and instruction books for cornet and clarionet; wanted History of the "Franco-Prussian War," and the "Lost Cause." C. W. Hughes, Shreve, Wayne Co., Ohio.

Send for exchange list of insects, especially Coleoptera and Lepidoptera. Philip Laurent, 621 Marshall St., Philadelphia, Pa.

I have Brown's heavy scroll saw attachment, worth $6, which I wish to exchange for a lathe chuck or offers. C. B. Russell, Waterbury Centre, Vt.

Will exchange magnets, electric battery, as good as new, cost £3 in England, for plating battery and materials, or offers. F. Whitehead, Box 55, St. Augustine, Fla.

American and foreign coins to exchange; state what you have. W. J. Allen, 126 Twenty-third Street, Brooklyn, N. Y.

To exchange, fine imported game fowls of the best strain for Fleetwood scroll saw, compound microscope, telescope, magic lantern, shot gun, or offers. E. Alexander, Johnstown, Fulton Co., N. Y. Box 47.

Wanted, scientific books, minerals fossils and Indian relics, in exchange for minerals, fossils Indian relics, shells, etc.; send for lists; correspondence in German and English. A. W. Baily, Box 712, Atlantic City, N. J.

J. T. Bell, Franklin, Pa., has set of ivory chessmen, German flute, six extra keys, value $12, books, etc., to exchange for magic lantern, music box, guns, revolvers, or offers.

Birds eggs and arrow-heads to exchange for fossils and minerals, and birds eggs; send for my list. Clement G. Burns, Salem, Col. Co., Ohio.

Minerals (zeolites, etc.), to exchange for other minerals; state what specimens you have to exchange. H. L. Clapp, 35 West Cottage St., Roxbury, Mass.

Cabinet mineral specimens of Idaho in exchange for books, minerals, curiosities, etc., etc.; send for list and state what you have to exchange. P. Clough, Junction, Lemhe Co., Idaho.

Type, in exchange for curiosities, fossils, etc. Geo. K. Fischer, 729 North 6th St., Philadelphia, Pa.

I have some stamps which I would like to trade for stuffed birds, birds eggs and nests; I am also open to an offer; send for list of stamps. A. G. G., Box 26, Summit, New Jersey.

U. S. and foreign postage and revenue stamps for others; U. S. match and medicine especially; send list or sheet and I will do the same. B M. Hammond, cor. Elm and Live Oak Sts., Dallas, Texas.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing. P. O. Box 178, Wattsburg, Erie Co., Pa.

Wanted, a hand or self-inking printing press, small size, in exchange for books, magazines, papers, etc. B. D. Howell, High Bridge, Hunterdon, Co., N. J.

Demas lathe sea shells, rubber boots, California woods, Young Scientist and paper shells, for stencil dies, boxing gloves, revolver, foils, book on navigation, and manly arts. A. W. Port, San Diego, Cal.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

Wanted, to correspond with some one living near the ocean beach; also some one living near any lead or copper mines. Ewing McLean, Greencastle, Ind.

Wanted back numbers of "American Naturalist" and "American Journal of Science and Arts" (Silliman's Journal), for beautiful specimens, named, of American ferns, mounted or unmounted. Box 16, Pine Plains, N. Y.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J.

Minerals to exchange for other minerals; state what specimens you have for exchange. Samuel Wynne, Box 54, Phoenixville, Pa.

Will exchange, for printing outfit or shot gun, 6 years Nos. of Scientific American, with Supplement of 1876, 545 foreign and U. S. stamps, Art of Swimming, Instruction in Shorthand, and other books. W. A. Smith, West Randolph, Vt.

Insects and butterflies from China; state what is offered in exchange. Edward Laurent, 621 Marshall St., Philadelphia, Pa,

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

Birds eggs, books, foreign stamps, a good hammock, and revolver, to exchange for birds eggs and works on birds. F. D. Brown, Gallupville, Schoharie Co., N. Y.

A magic lantern with eight slides, cost $5, and other things, to exchange for scientific books, chemicals, or chemical apparatus, etc. A Campbell, Box 31, Derrick City, McKean Co., Pa.

Contributions to the Extinct Vertebrate Fauna of the Western Territories, by Joseph Leidy, Vol. I, in exchange for a similar work on Botany. F. O. Jacobs, Newark, Licking Co., Ohio.

Color.

If we admit a beam of ordinary white light (sunlight) into a darkened room, and let it fall upon a triangular prism, it will be separated into different kinds of light, and these received upon a white screen will give us the solar spectrum with its familiar rainbow colors. It is thus separated because the shortest light waves are deflected more from their original course by the prism than the longest waves.

Accordingly we find the red light least refracted, and following it in succession come orange, yellow, green, blue, and violet, the last being at the opposite end from red. Indigo as a distinct color of the spectrum is now disregarded. If we select by the most careful process a beam of one of the colored lights from the spectrum, and let it fall upon a second prism, we shall find that it remains unchanged; therefore, these colors being incapable of further analysis, have been called primary colors. We can, however, produce any of these colors by a proper combination of three of them, viz.: red, green, and violet, which Dr. Young first pointed out as the true primary colors. It is still an open question whether violet or blue is to be considered as the third member of the group. Red, blue, and yellow cannot be regarded as primary colors, for it is impossible to produce green light by the combination of blue and yellow light; they produce white light. On the other hand, yellow light results from the mixture of red and green light; blue light from the mixture of green and violet, and orange from red and yellow; so that we have thus all the colors of the rainbow.

Since red, green, and violet can be thus combined, they can, of course, also be so combined as to reproduce white light; but white light can be obtained not only by combining these three directly, but also by combining yellow and a proper hue of blue, since blue is composed of

violet and green light, and yellow of red and green; or we can combine yellowish-green and violet, and so on.

We have seen that white light may be produced by combining two colors; two such colors are called complementary colors, and the study of complementary colors is of great importance to the artist. The complementary color of red is bluish-green; of orange, sky-blue; of yellow, violet-blue; of vioiet, greenish-yellow; of green, pink. There are certain laws of harmony and contrast in color, which the artist must know. Simple contrast exerts an important influence, since it heightens the effects of colors, if complementary. Thus green appears brightest by the side of red, or violet beside yellow; but if mixed, such colors destroy each other, producing grey. Two colors, not complementary, if placed side by side, diminish each other's effect. If two colors are placed side by side, each will be modified, as if mixed with the complement of the other. Thus, if red and blue are placed together, the blue will receive a tinge of green, the complementary of red, while the red will receive a tinge of orange. It is by this contrasting of colors that the artist produces his most subtle effects, lowering or strengthening one color by working upon its neighbor. The light in which we view a color affects it; blue drapery under the cold light of the northern sky is heightened by the light; but if the light is orange, as from a brilliant Southern sun, the blue is bluer in the shade than in the light.

A tasteful person will always observe these principles, and, in dressing, combine colors which enhance each others effect. A rosy face is made still fresher by a green dress or bow; a green dress looks well with a red scarf; but no one would ever wear a purple dress with blue trimmings, or throw a scarlet shawl over a crimson dress.

We will only pause to consider two facts previously stated. We have seen that yellow and blue light produce white when mixed, and yet we know that if we mix yellow and blue paints we get green. To explain this we must remember that these paints consist of more or less transparent particles, and the light which comes from them to our eyes is reflected partly from their inner surfaces, or from the paper below. They produce, therefore, the same effect that would be produced by looking through a piece of blue glass and a piece of yellow glass together. The blue glass is transparent only to green and violet rays, with their resultant, blue; while the yellow glass transmits only red and green, with their resultants, orange and yellow; hence only the green light can pass through both.

The second fact is that the same object, illuminated by the same light, may appear of different colors to our eyes under different conditions.

If we look steadily for one or two minutes at a bit of bright red paper on a white background, and then quickly remove the red paper, we perceive a bluish-green spot on the background, which to the eye, in its normal state, would have appeared pure white. We have fatigued the red nerves, and when suddenly exposed to the white light they fail to act, hence the sensations of green and violet light only are produced. If we fatigue the violet and green nerves by looking steadily at a bluish-green spot, and then quickly look at the purest red color of the spectrum, it will appear of a purer red than we can obtain in any other way. Employing this principle, the artist can give a green tint to a white spot on his paper by surrounding it with red.

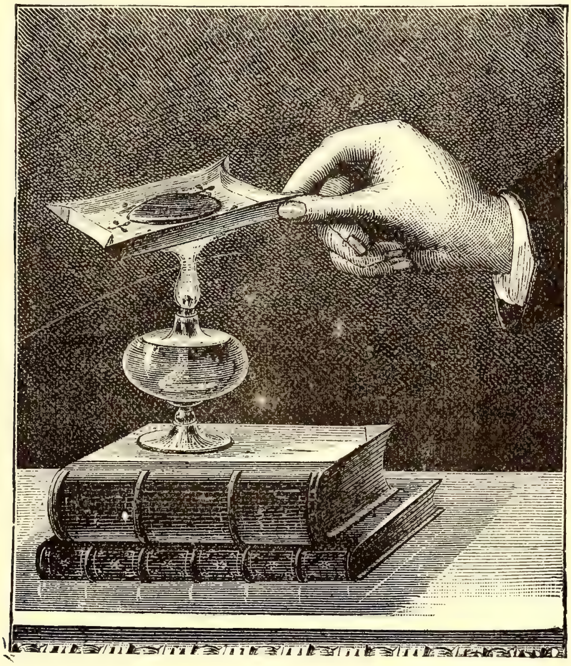
Curious Experiments With Fire.

In a former article we showed how water might be boiled in a paper vessel by simply holding it over a lamp or candle. In this case, however, the paper is thin, and the water carries off the heat so rapidly that the outside never has *time* to get hot. If we were to make a large vessel, capable of holding several gallons, of a material like paper, it would be so thick that the heat would not pass through it quickly enough, and the outside would burn while the inside was cold. Try to boil water in a wooden pail by holding it over a fire, and see what poor work you will make. But the In-

dian boils water and makes soup in a basket! The basket is so well made that it is water tight—just like a wooden pail, and holds water or soup, or any other liquid! But he does not hold the basket over the fire; he puts the fire in the basket, and he does this by heating smooth stones quite hot, and then plunging them in the liquid. In this way he soon makes the water boil.

As a curious example of heating water in a wooden vessel, we may mention the first steam boilers made in this country. Iron was then scarce and dear, and the facilities for working it were not very good, so Oliver Evans made his steam boilers of wood, just like so many barrels, and through them he passed iron tubes. These tubes conveyed the flame and hot smoke, so that the water was quickly heated and steam raised. On the whole, although they were not equal to our modern iron and steel boilers, these wooden boilers were very serviceable.

Another curious problem may be stated thus: To boil water in a common tumbler over a lamp or gas flame. This is easily accomplished as follows: Over the mouth of a tumbler full of water place a sheet of close-grained paper; press it on tightly, and quickly invert the tumbler. Instead of the water falling out, it will remain in place, and the paper will not fall off. The inverted tumbler may then be held over the lamp, when the heat will pass readily through the paper, which will not be burned, however, and the water will quickly become hot. And now comes a curious point in this experiment. As soon as the water boils and steam is formed above it in the tumbler, the pressure of the air, which formerly held the paper and water in place, is counterbalanced, and both paper and water fall to the ground. To prevent this, if we desire to carry the heat to the boiling point, we must *tie* the paper firmly over the mouth of the tumbler, and we can then raise the water to the boiling point with safety. But we must not make it any hotter than



MELTING METAL IN A CARD.

boiling, or our cover will be blown off, since we have here a veritable steam boiler, of which the paper cover is the safety or rather the *danger*-valve.

The most extraordinary experiment (next to stirring molten lead with the naked hand, a feat which we will explain hereafter) is that of laying a piece of fine cambric or thin muslin on a red hot coal without burning it! This is easily done by stretching the fabric tightly over a polished metal ball before bringing it in contact with the coal. The metal will conduct the heat away so rapidly that it will be impossible to burn the cambric.

So, too, a piece of lead, tin, or any similar metal may be melted in a thin cardboard dish by holding it over a lamp, as shown in the figure. The only condition that is necessary is that the metal shall melt at a temperature below the point at which cardboard burns. Common solder is a good metal with which to try the experiment. We might use fusible metals, some of which melt at a temperature less than that of boiling water, but this would not be a fair illustration of the principle we are illustrating.

A Talk About Bows and Arrows.

"YOU see," said Dr. Carver, as he deposited a whole sheath of brightly feathered arrows on a table, took off his umbrageous felt, and drew up a chair, "I must be shooting something or other all the time. If it isn't a Winchester, it's a bow and arrow. Pretty, they are. But most too fine! Fancy thing, these arrows, for handsome young ladies to shoot on grass plats at straw targets. Now an Indian arrow is a good bit longer—maybe 32 inches—and when a Sioux draws it chock up to the bow it fairly hums when he lets it fly. An Indian arrow has grooves cut in it behind the barb—that is to say, the ones they use in hunting—so that the blood can flow, otherwise the wound would spoil and swell. The fighting arrows are nasty things. The barb is so put on the shaft that when it hits you the steel, or old hoop iron, stays in the flesh when you go to pull out the arrow. Dear sakes, what ugly wounds I have seen them make! An Indian boy begins to handle a light bow when he toddles, maybe at four or five years. His bow is taller than he is. He shoots at almost anything around the camp. When he is twelve he uses sharp arrows. A boy must be strong at eighteen to use a man's bow. Now, a white man who takes an Indian bow for the first time has all he can do to bend it. It wants some strength, but more knack. The bow is made straight. When it is strung, the cord, even when in tension, almost touches the bow. It is thick, some four and a half to five feet long—that is, their hunting bow—and has extra stiffness by having sinews pasted on it. I have seen We-shessa-has-ka—that is the Long Man—and he was the best of the Ogalalla Sioux, kill an antelope with his arrows at 125 measured yards. We-shessa-has-ka was nearly seven feet tall, and a good Indian. On horseback, broadside to a buffalo, I have more than once known that Indian to send an arrow through a big cow. The arrow hung out on the other side. The bow for horseback and for war is a trifle shorter, and may be stiffer. You do not draw the arrow to the eye, but catch aim as I do when shooting from the hip. That can be acquired only by long practice. The string is drawn by the clutch of the whole fingers, though some of the tribes use the thumb and three fingers. The long man could shoot an arrow in the air out of sight, and so can I (the doctor pointed to an arrow buried up to the feathers in the ceiling of our office, his own peculiar ornamentation of the Forest and Stream sanctum). I think that in a couple of months I could get into perfect practice, for I used to hold my own with any Indian on the plains. Sometimes, after I had been shooting with my Winchester, an Indian would come up and show his bow, and tell me his bow was 'muchee good;' but then I used to take his own bow and beat him at it.

To pass away the time when I was at the Brooklyn Driving Park, I bought an English bow and arrows of Holberton, and soon got into the trick of it. I hit blocks of wood thrown into the air quite as often as I missed them. The English bows and arrows are fancy, but good. I

would rather have an old Sioux one, made of hickory or ash, but the boss bow I ever owned was made of buffalo ribs. An Indian carries his quiver of arrows over his right shoulder, so that he can get his arrows quickly. When he has discharged one arrow, with the same motion that he uses in pulling the string he clutches another arrow. If he shoots one hundred yards he has three or four arrows in the air all going at the same time. It's great fun shooting at a bird with a long tail that flies over the prairie. Knock out his tail and his steering apparatus is gone. I have knocked the tail out of many a one, and so caught him in my hands when he tumbled."—*Forest and Stream.*

Cheap Lathes and How to Use Them. III.

HOW TO CHOOSE A LATHE.

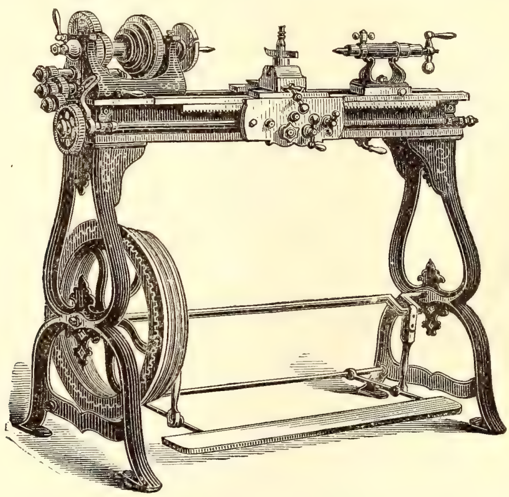
HAVING decided as to the size and general character of the lathe that will best suit our requirements, the next thing to be done is to select from those in market a well-made sample of the kind of lathe that is wanted.

If the lathe be a very cheap one, it must not be expected to be perfect in its parts and movements. Still, even in this case, the spindle should run easily, the balance wheel should have sufficient weight, and the framework should be firm and without shake. To test the movement of the lathe, whether it be cheap or dear, throw off the band and turn the spindle by hand. It should move very easily and yet without shake, and when tightened a little in its bearings, so that it runs just a trifle stiffly, it should move quite as easily at one part of its revolution as at another. The latter is a principal point to be attended to in all lathes. If the spindle moves easily and freely for half a turn, and then binds and becomes stiff in its movements, it shows that spindle and bearing are not round and true. This is a very bad defect, and it can be detected only in the way we have pointed out, viz., by throwing off the band, tightening the bearings of the spindle, and turning the latter by hand. So long as the band is on, especially if it be pretty tight, the spindle will be held down so that it will show no shake to the hand; but the moment it is used for work, and the chisel is applied to the article that is to be turned, the band becomes unequal to the task of holding it down, the piece that is being turned will jump, and the work will be untrue. All this shows itself when the band is no longer in place to keep the spindle down and make it run *apparently true.* In a well-made lathe you may tighten the bearings of the spindle until you can hardly turn it, and still you will find that it moves without any perceptible difference throughout the entire revolution.

The fly-wheel next demands our attention. The temptation to make this part very light, and thus save material, is strong, but when yielded to, it works nothing but evil for the purchaser. In very light lathes the fly-wheel and treadle may be built on the sewing-machine plan, and indeed an old sewing-machine stand sometimes answers very well for a very light bench-lathe. In this case the fly-wheel may be light, because it is driven on both the upward and downward motion by the foot—the treadle being so arranged that the foot *rocks* instead of having a clean sweep up and down. But it is impossible to get much power in this way, and in most lathes the treadle is so made that the foot moves up and down, and the fly-wheel is driven only through half a revolution, the other half being accomplished by its own momentum. If, therefore, the fly-wheel has not weight enough to carry it round with a speed almost as great as that which it takes on the down stroke of the foot, the motion will be variable, and the work will be untrue. The only way to secure equable motion in the fly-wheel, is by weight; see, therefore, that it has it.

Some of our readers may, however, already own a lathe with a very light fly-wheel. This may be remedied by wrapping the arms with lead, or by screwing blocks of metal to the wheel. The young workman will, of course, see that this additional metal is so distributed that the wheel is not made heavier one side than on another, and he will also take care that the extra material is so firmly secured that there is no danger of its flying off.

There is, of course, a limit to the power that can be obtained from the foot and fly-wheel alone, and this limit is a comparatively narrow one. Where the amateur desires to turn up heavier articles, particularly pieces of metal of considerable size, he must have recourse to gearing, and he will then select either a simple back-geared lathe, as it is called, or, if his means will allow it, a complete self-acting lathe, such as is shown in the engraving. Such a lathe is not by any means a *cheap* lathe, but we introduce a figure of it here for the purpose of showing what is necessary to constitute a *complete* lathe, and thus to point out to our readers what they must *not* expect from the incomplete tools which are sold at a low price. In the lathe shown in the engraving, the driving parts may be so arranged that the spindle is not driven directly by the belt, but by the large gear-wheel at the right-hand end of it. This wheel is driven by a pinion on the same spindle which carries the large gear-wheel to the left, and this latter wheel is driven by a pinion on the cone which takes the belt from the fly-wheel. It will be seen that a very fast motion of the fly-wheel and cone is reduced to a very slow motion of the spindle, and of course the power (as it is sometimes called) is greatly increased. By means of this arrangement we have been frequently able to take off a heavy cut from an iron bar two or three inches in diameter in a foot-driven lathe.



SELF-ACTING FOOT LATHE.

How to Make a Pretty Basket.

MAKE a basket of wire; see that it is symmetrical and in good shape. The wires may be tied with woollen yarn at their junction with each other. Twist round the wires, at given points, woollen yarn. Make a hot solution of alum water; make it as strong as possible. Suspend the wire basket in the solution, so that it will not not touch the vessel, but will be wholly covered by the liquid. Let the basket remain still in solution for twelve hours, when it will be found that the alum has crystallized over the whole surface of the basket in a most beautiful manner. This gives a white or frost-like appearance; for other tints the following coloring substances may be employed: For yellow, turmeric; for red, solution of litmus; for purple, logwood; for blue, a solution of soluble Prussian blue; for green, the first and last mixed to suit taste. These coloring substances should be mixed with the solution while it is hot. The colored crystals are much more easily destroyed than those of pure alum. The best way to keep ornaments of this

kind clean is to place them under glass shades. Other things than baskets may be ornamented by this process, such as wire easels for pictures, match-safes, etc., etc.

Three Amateur Workers—and What They Did—VIII.

BY FRED. T. HODGSON.

THE body of the house being put together, and the partitions being marked off and placed in proper position, it became necessary to make provision for the roof. This was done by taking

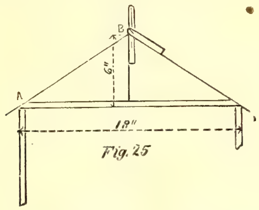


Fig. 25

two boards, twelve inches wide and three feet four inches long, and beveling one edge of each to the angle shown in Fig. 25. A shows the proper angle to bevel the pieces; B, the bevel made on the top of the house to receive the roof. The figures explain themselves. Mr. Carpenter made a diagram or plan the full size, on a planed board, with a lead pencil. This enabled the boys to get the angles and sizes exactly, which they did without any trouble.

The boys left the boards four inches larger than the house, in order to allow the roof to project two inches over each end, the same as on the sides. After the roof was placed in position and nailed on to the top of the honse, on a line with B, Fig. 25, it was found that the gables at each end were open, and pieces of thin stuff were cut the right shape to fill the opening, and drop down low enough to nail on to the ends of the house. This being done, it was decided to have a gable or pediment in front, to "set the house off," as Ellwood termed it, and in this gable a window was cut, as appears in Fig. 26, which shows the house just as it appeared when finished, all but the front.

This engraving (Fig. 26) is on a scale of one-sixteenth of an inch to one inch; that is, each one-sixteenth of the cut, measured in any direction, equals one inch actual measurement on the house. If you measure across the picture, you will find that it is just two and a quarter inches, or 36 sixteenths of an inch; well, the house, as built, just measures thirty-six inches.

Mr. Carpenter fully explained this matter to the boys, and showed them that any part of the picture was just one-sixteenth of the size of the corresponding part on the house as built.

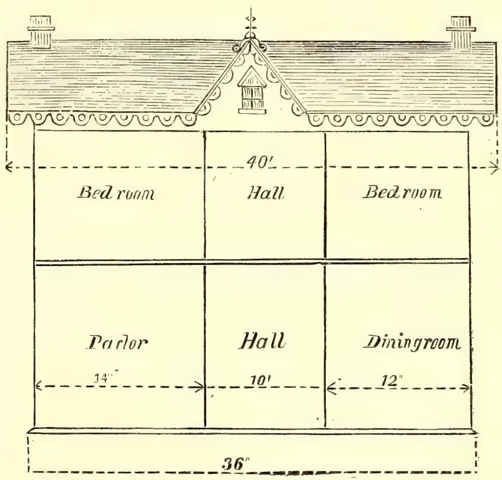

Fig. 26.

As the house now stood, bare and open in the front, it did not present a very nice appearance, and Jessie seemed somewhat disappointed at its looks. She soon made known her feelings by asking her father "if that was all that was going to be done to her dolly's house?"

"Why no, my dear," said Mr. Carpenter, "we are going to put a front on it with five windows and a hall door, and then we will paint the body olive-green, and the trimmings of the windows, door, and cornice a deep Indian red. The front will be made in two pieces and hinged on the sides. It will part on a line with one of the partitions. When you wish to see the inside or adjust any of the furniture, you may open one or both sections of the front. Of course, Jessie, you will have to

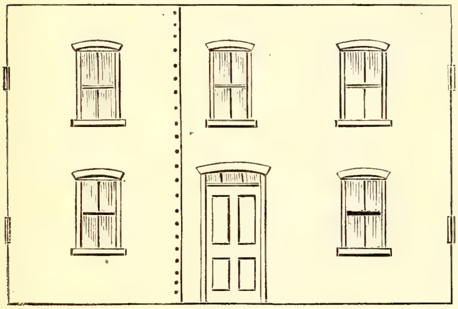

Fig. 27.

paper all the rooms and ceilings yourself, and according to your own taste."

Jessie was quite pleased with this explanation, it was all she required; and she began to form plans in her own mind for furnishing and decorating her new house.

Several evenings elapsed before the house was complete. Two chimneys had to be made of thin stuff, and in proportion to those shown in the cut, Fig. 26; they were painted red and striped like brick work. A flight of stairs was put up in the hall, and Fred sawed out an ornamental baluster and rail for the stairs all in one piece, with newel post and side string. All this work was done with the new scroll saw; and the wavy pieces and scroll ornament on the gable were cut out with the same tool. The windows were cut out of the "solid," and strips of tin were run across the openings on the inside, and nailed with small-headed tacks. These strips of tin were about three-sixteenths of an inch wide, and represented the sash bars; sheets of glass were then placed over the strips, and other tin strips were then run over the inside of the glass and nailed down to the wood close to the edges of the glass. These second strips represented the sash bars on the inside, and answered the purpose of holding the glass in its place. These strips were painted in appropriate colors on both sides of the glass.

At the entrance a front door was represented by painting, but the fanlight over the door was cut out of the "solid," like the windows, and was treated the same way, only that the glass used for the purpose was colored.

In cutting the openings for the windows and fanlight, it was necessary to first mark them out the size required. When this was done, a hole was bored in one

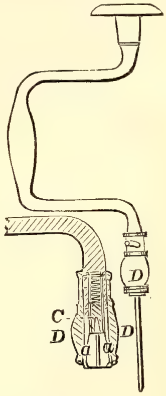

Fig. 28.

corner with the brace and bit (Fig. 28), into which the point of the key-hole saw (Fig. 29) was inserted, and the opening

Fig. 27 shows the front. It is made of stuff half an inch thick, and is in two parts, being divided at the dotted lines. Each part should be hinged to the sides of the house with small hinges, which are placed about as shown in the cut. The doors may be held closed by a "button," or any other suitable device.

Fig. 28 shows an iron brace with bit inserted. *a a* show the jaws, which are opened and closed with a sleeve nut, D. The end of the bit presses against a movable centre-piece, which has a spring behind it.

was made larger by sawing close to the lines. A little difficulty was met with

Fig. 29.

when the saw had travelled to the corners; it was found that the saw would not turn at right angles and leave a nice square corner. This trouble was got over by first sawing "square up into the corner," and then taking the saw back about an inch from the angle and starting it in the wood again, and making a short curve with it until it struck the line. The sawing was continued in this direction until the next angle was reached, when the saw was taken out and turned with its teeth in a contrary direction, and the little curve in the corner just passed was cut away. All the other corners were treated in a similar manner.

The house proper was finished, so far as the boys were concerned, but, as they had promised to make furniture for it, they had still plenty of work on hand, and Jessie was quite anxious, now that the house was built, to get it furnished and completed; so it was decided to go right to work at the furniture.

Let us see how they get along!

(To be continued.)

The Water Telescope.

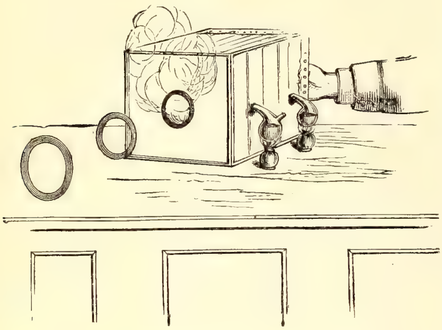
THIS efficacious and cheaply-made instrument is not used so much in this country as its merits deserve. The Norwegian fishermen are constantly in the habit of employing it in their herring and cod fisheries, and often thereby discover shoals of fish that would otherwise escape their nets. On the surface of the water in the sea, and also in most rivers, there is generally a ripple, which prevents the bottom being seen; it is to get rid of this ripple that the water-glass is so useful. There are two forms of water glass—namely, an ordinary bucket or barrel, with the bottom knocked out; second, a piece of tin of a funnel shape, about three feet long and nine inches diameter at the broad (or bottom) end, and large enough at the top to accommodate the observer's eye—into the broad end should be inserted a plate of strong glass, and some lead to weigh it down. When the water is clear this instrument will enable the observer to see from three to twenty fathoms on calm bright days. Of course when the water is muddy or discolored the glass is useless. The Cornishmen, especially at the Landsend, use these instruments for looking for wrecks, lost crab and lobster pots, etc. To the naturalist they will be invaluable, as by means of them the actions of the fishes and other inhabitants of the ocean can be observed better than in any aquarium. The beauties and luxurious growth of the submarine forests of sea plants will also to many be a most novel and interesting spectacle. To water parties who picnic on rivers or near lakes, the water telescope will be found a great addition to the day's enjoyment, as by means of it subaqueous scenery may, possibly for the first time, be brought into view, and many a panorama opened up to the human eye quite as beautiful, if not more so, than many a view in distant countries where friends and relations are enjoying an expensive tour.

Fig. 29 shows a keyhole or pad saw. The blade is quite thin, and not more than ⅛ of an inch wide at the point. It is fixed in the handle by two set screws, which are adjusted by a screw-driver. A narrow slot runs through the handle, in which the saw may be lengthened or shortened.

Smoke Rings.

IN a former number of the YOUNG SCIENTIST we described a very simple device for showing the curious "smoke rings" which are produced when air, loaded with visible smoke or vapor, is expelled in puffs from any reservoir. The engraving shows a larger and more effective device for the same purpose. A cheap box (a small tea chest answers very well) has a hole bored in one end, and over the other is tacked a piece of stiff paper. Through two small holes in the side are inserted the nozzles of two small tube retorts, one containing hydrochloric acid, and the other strong liquid ammonia. The retorts are heated by two small lamps, and the vapors that are given off

meet in the box and combine, forming a dense white vapor. When the paper or membrane covering the end of the box is tapped smartly with the finger, the air and vapor rush out of the hole at the opposite end, and form magnificent white



SMOKE RINGS.

rings, which travel quite a distance, expanding and curling in a most beautiful manner. The experiment is one that is easily carried out, and it never fails to please. The arrangement we have figured is one that is well adapted to the lecture room.

Bird Paste.

Bechstein, a celebrated German ornithologist of the past generation, recommends the following pastes, both of which soon become sour, but the formula can be easily modified so that the food could be kept as a dry powder, which would not alter:

No. 1. Take a stale well-baked white loaf, soak it thoroughly in fresh water, squeeze out the water, and pour boiled milk over it, adding about two-thirds of well-sifted barley or wheat meal.

No. 2. Grate a carrot very finely, soak a small white loaf in water, squeeze it out, and put it with the carrot in an earthen pan, add two handfuls of barley or wheat meal, and mix thoroughly.

"The first paste," says Bechstein, "agrees so well with all my birds, that they are always healthy and preserve their feathers, so that they have no appearance of being prisoners. Sometimes, as a delicacy, they are given ants' eggs, or a few meal worms."

Mr. Sweet recommends the following: Hemp seed crushed very small, in boiling water, is mixed thoroughly with an equal quantity of bread soaked and squeezed dry, and an equal quantity of lean raw meat minced fine. Another authority says that, for the lark, barley meal, with cabbage, chopped cress and poppy seed, mixed with bread crumbs, or in winter with oats, forms a good food.—*Chemist and Druggist.*

Plating and Gilding Without a Battery.

A very useful solution of silver or gold for plating or gilding without the aid of a battery, may be made as follows: Take, say, one ounce of nitrate of silver, dissolved in one quart of distilled or rain water. When thoroughly dissolved, throw in a few crystals of hyposulphite of soda, which will at first form a brown precipitate, but which eventually becomes redissolved, if sufficient hyposulphite has been employed. A slight excess of this salt must, however, be added. The solution thus formed may be used for coating small articles of steel, brass, or German silver, or by simply dipping a sponge in the solution and rubbing it over the surface of the article to be coated. I have succeeded in coating steel very satisfactorily by this means, and have found the silver so firmly attached to the steel (when the solution has been carefully made) that it has been removed with considerable difficulty. A solution of gold may be made in the same way, and applied as described. A concentrated solution of either gold or silver thus made, may be used for coating parts of articles which have stripped or blistered, by applying it with a camel-hair pencil to the part, and touching the spot at the same time with a thin clean strip of zinc.—*Exchange.*

Preservation of Wood.

In speaking of the well-known methods of preserving posts and wood which are partially embedded in the earth, by charring and coating with tar, it is said these methods are only effective when both are applied. Should the posts be charred only, without the subsequent treatment with tar, the charcoal formation on the surface would only act as an absorber of the moisture, and, if anything, only hasten the decay. By applying a coating of tar without previously charring, the tar would only form a casing about the wood, nor would it penetrate to the depth which the absorbing properties of the charcoal surface would insure. Wood that is exposed to the action of water, or let into the ground, should first be charred, and then, while still hot, be treated with tar till the wood is thoroughly impregnated. The acids and oils contained in the tar are evaporated by the heat, and only the resin left behind, which penetrates the pores of the wood and forms an air-tight and water-proof envelope. It is important to impregnate the poles a little above the line of exposure, for here it is that the action of decay

affects the wood first, and where the break always occurs when removed from the earth or strained in testing.

Hard Colored Cements for Inlaying.

Colored cements are used to give cast goods of zinc or brass the appearance of buhlwork, and to fill up the holes made by etching in zinc door plates, street numbers, coats of arms, etc. They are also, with advantage, employed for making casting-models of more artistic objects, as well as for mosaics on metal ground; but they may be further found useful in engineering works for isolaters, large rings and plates. According to Stach, the following process gives good results: A solution of soluble glass of 33° Baume, is mixed with fine whitening, with the addition of the materials mentioned below, until it assumes the tenacity of a thick plastic mass, and thus different colored cements, hardening in six or seven hours, of considerable strength, and very useful for the purposes above quoted, are obtained. By adding gray-sulphuret of antimony a black cement is obtained; this may be polished with agate, and has a metallic onyx-like luster. Another black cement is prepared by mixing equal parts of sulphuret of antimony and iron filings (finest) with the above soluble glass; but the cement can only be ground. Carbonate of copper, pure chrome green, give green; cobalt blue, blue cements. (Ordinary ultramarine is not fit for use, because it decomposes and scatters the mass). Red lead gives orange cement, sulphide of cadmium citrine, cinnabar bright red, and cochineal-lac violet cement; zinc dust and alcoholized iron give a brown cement, and powdered manganese acts in the same manner. An especially valuable gray cement, which may be polished with the agate to a metallic luster, and used in the repair of damaged zinc ornaments—whether cast or of sheet zinc—is produced by mixing pure most finely-sifted zinc dust with soluble glass. Hitherto these mixtures have been used solely for imitating marble, but the cements are also of great value in the metal-ware industry.

Practical Hints.

Bronzing-Liquid.—Ten parts of aniline red and five parts of aniline purple are dissolved in 100 parts of 95 per cent. alcohol, on the water-bath, and the solution, after the addition of five parts of benzoic acid, boiled (for 5-10 minutes) until it has changed its greenish color to light bronze-brown. Applied with a brush upon *leather*, metal, or wood, the liquid produces a magnificent bronze coating.—*Bayr. Ind. und Gewerb. Zeit.*

Mica.—To the microscopist a world of interest may be found in the micas. They frequently contain between the layers microscopic crystals of minerals, some of them, especially with polarized light, forming specimens of wonderful beauty. Of most minerals, sections for microscopic examination must be made by the laborious process of grinding and polishing, but in mica we may almost say the sections are made by nature, and the time required to make one section of most minerals will make at least 100 of mica, and the thickness or thinness is a matter of perfect control.

To Color Horn Black.—C. Burnitz, of Stuttgart, uses the following method of accomplishing this without subjecting the material to a boiling heat: The articles, after being made ready for polishing, are to be placed in a lye of caustic soda, or potassa, till the upper strata of the horn have been dissolved to such an extent that the articles feel greasy to the touch. With care, even the finest tooth-combs may be thus treated. The articles are now washed in water, and drawn through aniline black, known as the Lucas aniline black, dried slowly, and then washed. The light passing through the horn has a deep-brown color; but by reflected light the article appears of a deep black.

Water-tight Parchment Paper Bags.—These are made by means of chrome-gelatin. A 15 per cent. solution of gelatin in water is warmed and mixed, *in the dark*, with a 3-5 per cent. solution of potassium bichromate. The mixture is poured into small black bottles, and kept carefully from the light, which would harden it and make it insoluble. Before use, the bottle is set into hot water, carefully preventing the access of daylight. When the cement is melted, the edges of the parchment-paper, which must have been wetted, are brushed over with the cement, and then rapidly dried in the sun. To test them they are filled afterwards with water and hung up in frames. Any hole which may be discovered is closed by means of the above cement.—*Pharm. Zeit.*

How to Clean Marble Top Furniture.—It may be of some value to housekeepers who have marble-top furniture, to know that the common solution of gum arabic is an excellent absorbent, and will remove dirt, etc., from marble. The method of applying it is as follows: Brush the dust off the piece to be cleaned, then apply with a brush a good coat of gum arabic, about the consistency of thick office mucilage, expose it to the sun or dry wind, or both. In a short time it will crack and peel off. If all the gum should not peel off, wash it with clean water and a clean cloth. Of course, if the first application does not have the desired effect it should be applied again. Another method of cleaning marble is to make a paste with soft soap and whiting, wash the marble with it, and then leave a coat of paste upon it for two or three days. Afterwards wash off with warm (not hot) water and soap.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

I have a new Munsen's battery, large size, which I wish to exchange for a good revolver or offers. Robt. T. Boyle, 351 West 83d St., New York.

Hair of American deer to exchange for diatoms, foraminifera, or other material. W. H. Osborn, Chardon, Ohio.

To exchange, full instruction in short-hand writing, and birds eggs, for birds eggs, postage stamps, or offers. M. F. E., 51 Spencer St., Albany, N. Y.

"History of Our Country," by Lossing, in six parts, price $15, to exchange for printing press or offers. Frank Chandler, Waverley, Mass.

Fine Devonian and Carb. fossils for others, especially cretaceous fossils, scientific books or papers; Pitman's short-hand works for books or offers. A. Stapleton, East Point, Tioga Co., Penn.

Wanted, scientific books and apparatus; send lists and say what is wanted in exchange. Ewing McLean, Greencastle, Ind.

Wanted, specimens in geology, entomology, oology, etc., for those in other localities, also coins and a charm microscope (magnifies 1,000 times) for one having a different view. J. H. Jones, Frankfort, N. Y.

For printing press or offers, achromatic telescope, $8.50; microscope, $5; set drawing instruments, $3; revolver, $3; Phrenological Journal, $2.50; books, 12 plays, farces, dramas, burlesques, etc., $1.80. F. E. Payne, Alma, Mich.

One pair 3 lb Indian clubs, one scroll saw, one pocket lantern, and a large number of books, for magic lantern, pair telephones, photographic camera, or offers. Thos. A. Black, Lock Box 678, Scranton, Pa.

For exchange, pocket lantern and instruction books for cornet and clarionet; wanted History of the "Franco-Prussian War," and the "Lost Cause." C. W. Hughes, Shreve, Wayne Co., Ohio.

Send for exchange list of insects, especially Coleoptera and Lepidoptera. Philip Laurent, 621 Marshall St., Philadelphia, Pa.

I have Brown's heavy scroll saw attachment, worth $6, which I wish to exchange for a lathe chuck or offers. C. B. Russell, Waterbury Centre, Vt.

Will exchange magnets, electric battery, as good as new, cost £3 in England, for plating battery and materials, or offers. F. Whitehead, Box 55, St. Augustine, Fla.

American and foreign coins to exchange; state what you have. W. J. Allen, 126 Twenty-third Street, Brooklyn, N. Y.

To exchange, fine imported game fowls of the best strain for Fleetwood scroll saw, compound microscope, telescope, magic lantern, shot gun, or offers. E. Alexander, Johnstown, Fulton Co., N. Y. Box 47.

Wanted, scientific books, minerals fossils and Indian relics, in exchange for minerals, fossils, Indian relics, shells, etc.; send for lists; correspondence in German and English. A. W. Baily, Box 712, Atlantic City, N. J.

J. T. Bell, Franklin, Pa., has set of ivory chessmen, German flute, six extra keys, value $12, books, etc., to exchange for magic lantern, music box, guns, revolvers, or offers.

Birds eggs and arrow-heads to exchange for fossils and minerals, and birds eggs; send for my list. Clement G. Burns, Salem, Col. Co., Ohio.

Minerals (zeolites, etc.), to exchange for other minerals; state what specimens you have to exchange. H. L. Clapp, 35 West Cottage St., Roxbury, Mass.

Type, in exchange for curiosities, fossils, etc. Geo. K. Fischer, 729 North 6th St., Philadelphia, Pa.

I have some stamps which I would like to trade for stuffed birds, birds eggs and nests; I am also open to an offer; send for list of stamps. A. G. G., Box 26, Summit, New Jersey.

U. S. and foreign postage and revenue stamps for others; U. S. match and medicine especially; send list or sheet and I will do the same. B. M. Hammond, cor. Elm and Live Oak Sts., Dallas, Texas.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing. P. O. Box 178, Wattsburg, Erie Co., Pa.

Wanted, a hand or self-inking printing press, small size, in exchange for books, magazines, papers, etc. B. D. Howell, High Bridge, Hunterdon, Co., N. J.

Demas lathe sea shells, rubber boots, California woods, YOUNG SCIENTIST and paper shells, for stencil dies, boxing gloves, revolver, foils, book on navigation, and manly arts. A. W. Port, San Diego, Cal.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

Wanted back numbers of "American Naturalist" and "American Journal of Science and Arts" (Silliman's Journal), for beautiful specimens, named, of American ferns, mounted or unmounted. Box 16, Pine Plains, N. Y.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

Minerals, birds eggs, shells, woods, stamps, nests, books, insects, etc., to exchange for coins, stamps, minerals, birds eggs, insects, and fossils; send for my lists. Frank F. Fletcher, St. Johnsbury, Vermont.

Wanted to exchange 1 copy of Instruction in Wood Engraving, or set of dozen prints, suitable for practice, for specimens of algæ or minerals. S. E. Fuller, 25 Bond St., New York.

Wanted, copy of book called Corner Cupboard, and other scientific books; state what is wanted in exchange. G. S. Griffin, Emporia, Kansas.

Mosses from Germany, Colorado, and Illinois, also plants, Phænogamous and Crytogamic, to exchange for other mosses, lichens, liverworth, or algæ, East and South. Prof. P. Fr. Shuelke, Box 128, Pekin, Ill.

A large number of books, papers, and magazines, to exchange for type, printing material, or offers. J. T. Jackson, Box 48, Metuchen, N. J.

Good Specimens of the 17 years' locust (17 year cicada), in exchange for any kind of insects, beetles, moths, or butterflies. Harry C. Beardslee, Painesville, Lake Co., Ohio.

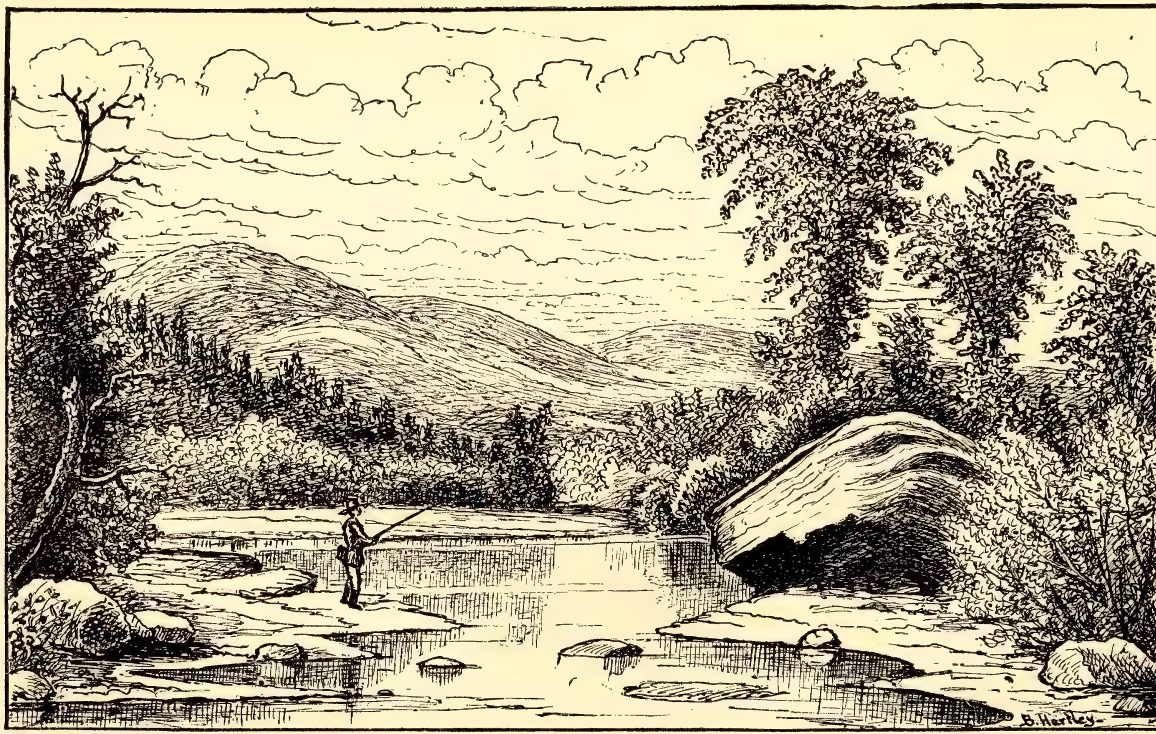


ILLUSTRATION OF COLLODIO-ETCHING. "Scene in the Catskills."

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. IV. NEW YORK, MAY, 1881. No. 5.

Collodio Etching.

ACCORDING to a promise made in a previous number, we give our readers an illustration which shows as nearly as possible the results that may be attained by the simple art which has been described in a series of articles under the head of *Collodio Etching.* Our illustration is a wood engraving, and the artist has endeavored to show in *facsimile* the special features of pictures produced by this process. It will be seen that the lines are singularly free and sketchy, thus giving to the whole design a boldness which is not found in ordinary engravings. Of course, in order to make such drawings, in the first place requires some skill and experience, but it is wonderful what a little perseverance will do, especially with the aids which have been developed by modern science and art—one of the most efficient of which is described in the next article, which is from the pen of the author of the previous articles on this subject.

It gives us pleasure to be able to announce that the author of the papers on Collodio Etching, which have recently appeared in these columns, has thrown a more extended and minute series of instructions on this subject into the form of a book, which we expect to publish in time for the use of summer tourists. It will form a neat little volume, handsomely illustrated, not only with engravings of all the apparatus used, but with actual illustrations of the process itself. To those who have a taste for drawing, and who desire an easy method of multiplying their sketches, this process offers unusual advantages.

—If a new shaft shows any signs of a crack, heat it at the spot to a low red heat, and drop a few drops of water upon the doubtful spot; and if it is cracked it will show plainly a black line along the crack.

Making a Picture Without Being Able to Draw.

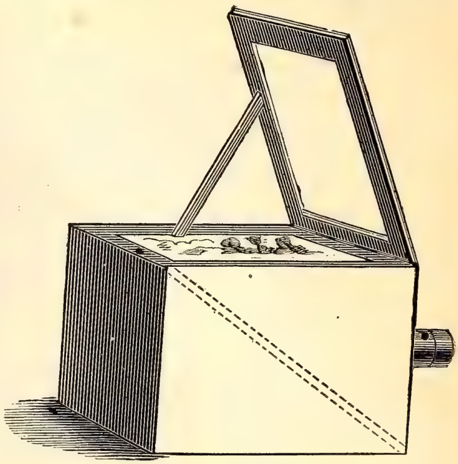
BY BENJAMIN HARTLEY.

THERE are many young persons who have not had the advantage of instructions in drawing, who yet have a taste for artistic pursuits, and would enjoy making pictures if only they could find some way to assist their uncultured eyes and hands. For the benefit of such we write this in the hope that some will be encouraged to try, and with the assurance, that if the advice given in this article is followed, will meet with considerable success.

Various means have been devised to overcome difficulties in the way of the youthful artist. The best assistant we think is a camera obscura, or sketching camera, as it is called. With such an instrument, used as we propose, almost any person might succeed in reaping very much of the pleasure to be derived from collodio etching without knowing the principles of drawing.

Like nearly everything else, the camera obscura may be a very plain, simple, inexpensive affair, or a very handsome and costly instrument. A boy scarcely twelve years old made one out of a thick pasteboard box and a common magnifying glass set in a pasteboard tube, which answered the purpose very well. We constructed one, some years ago, out of a starch box. This box was six by nine inches deep. Making a round hole in one end, a common single landscape lens, with tube from a small photographic camera, was inserted. The lid was taken out and a piece of a looking-glass, cut to fit, was placed inside, slanting downwards from back to front, so that the rays from the lens are reflected upwards. Now, in order to see the picture, we fitted a piece of ground glass in place of the lid. A light frame was next made and hinged to the top of the front, so as to fall backwards and cover the ground glass, and to this was tacked a large piece of black velvet, which was thrown over the head to exclude the light. This frame is supported on the left side by a stick screwed to the side of the box. A square box is better than an oblong one. All this can be easily understood by looking at the accompanying sketch. The dotted lines represent the mirror inside the box.

Suppose you have such an instrument, all you need to do is to put a prepared



plate, thinly varnished, on the top of the ground glass—varnished side up, of course—and trace the picture with a needle. If you wish to substitute the prepared plate for the ground glass, so as to get the image sharper and closer to your point, you must employ a varnish called "ground glass substitute," used by photographers. To this you must add about one-third more alcohol.

The picture thus made is reversed and ready for printing, and, besides, is a drawing *direct* from nature.

One thing more to be considered, and that is how to support the camera while working. For this purpose you will find a tripod the most convenient article. The camera must, in some way be fastened to the top, so as to remain perfectly still. Photographers use a bolt with screw and nut, but there are other ways of accomplishing the same object.

Messrs. Queen & Co. make and sell a little camera obscura with a tent, which is highly recommended for use by those unacquainted with drawing. By this instrument the picture is thrown down on a table inside the tent, and is sketched very easily, the principal trouble being the shadows cast by hand and pencil. It is not adapted to our purpose, however, as

we must have the light reflected from below the plate.

With the camera above illustrated and described, and a number of prepared plates, any one, with a little practice, can fill a day or a week at home or abroad, with profitable pleasure.

There are only two drawbacks to this practice: The first is the lack of artistic freedom. All you can do is to copy what is thrown on your plate; this can be overcome by an artist, but should not be attempted by any one else. The second disadvantage is in being unable in many instances to find a good standing place for the tripod, so as to get just the view you wish; but the great advantage of being able to etch your plate on the spot where a suitable place can be obtained, knowing that it is absolutely true to nature, will, in most minds, more than compensate for the disadvantages spoken of.

Let me, in closing, recommend the making of simple outlines first. A well-drawn outline is far better than a poorly-shaded picture, and can express a great deal more than is often imagined. After some practice in shading with a pencil, you can easily add it on your plates.

Frogs for the Aquarium.

BY A. W. ROBERTS.

NEXT to the young of the bull frog, the most desirable variety of the frog family for aquaria is the leopard frog, Fig. 1, which is generally acknowledged to be the handsomest of all our native frogs. In habit he is less aquatic than the bull-frog, often being found long distances from water; but in the spring of the year, during the breeding season, it remains near the water. The tadpoles of this frog cannot be distinguished from those of other frogs, and are, undoubtedly, more scarce; out of all the tadpoles of various kinds of frogs that I have raised, I never obtained a leopard frog, and from this I judge it is much less prolific than other varieties. I have known of large quantities of these frogs being taken in the winter time, in spring holes, for the New York Market. They are then in a semi-dormant condition, in which state they emit a decidedly strong, unpleasant, and pungent odor, but, when skinned and cooked, the odor disappears, and they are quite palatable. This is not so bad, however, as sending toads legs to the New York market, mixed up with a few frogs legs, and yet I have seen the remains of thousands of toads that had been slaughtered for this purpose.

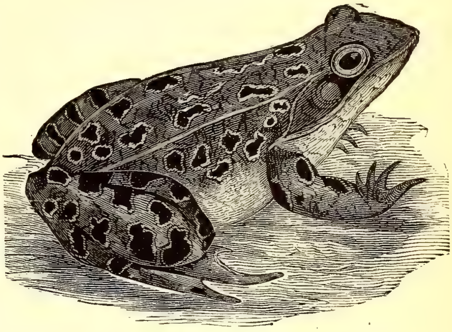


Fig. 1.—THE LEOPARD FROG.

The smallest of all frogs is the tiny tree frog, or Pickering's Hylodes, Fig. 2. This beautiful little reptile ought to be in the possession of every owner of an aquarium. A dozen to one tank of medium size is none too many. To keep these frogs in good condition in the aquarium, the surface of the water must be partially covered with bladderwort or duckweed, so as

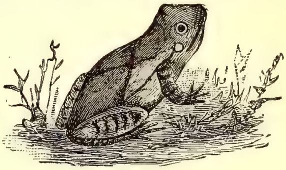

Fig. 2.—THE TREE FROG.

to afford them a resting place. The top of the tank must be provided with a close-fitting frame, on which is stretched fine netting, to prevent their escape. During the spawning season the voice of this frog is constantly heard along the margins of ponds, and consists of a shrill piping note. This piping they continue more or less through the summer season. In color they are changeable; and, as a rule, take on the colors of surrounding objects. When sick, or under the influence of

fever, they turn pale. When in repose, and resting on aquatic plants, they are of a dark greenish brown on the back, with two stripes of light green crossing near the middle; the sides are of a light green, vanishing into a yellowish white on the belly. Their toes are provided with soft membranous discs, by which they can adhere to any object, or climb a perpendicular surface. They are very delicate and easily killed. When collecting them, it is always best to place them in a separate vessel or compartment containing wet aquatic plants. They cannot live long in water, like other varieties of frogs, but are very easily drowned. I once had a tank containing over a hundred of these noisy little fellows, and it was very amusing to watch them, when piping, swell out their vocal organs to nearly the size of their bodies. Their favorite food was angle worms cut up fine, house flies, ants, and spiders.

Hints on the Use of Philosophical and Chemical Apparatus.

IT is, unfortunately, too true that most of our schools are destitute of the means of illustrating the principles which are set forth in our ordinary text books on chemistry and natural philosophy. At the same time it is also true that in every section of our country there may be found, connected with the public schools, sets of apparatus which are never used, or, if they are brought out at all, it is merely on distant occasions, and more for the purpose of complying with the requirements of trustees, etc, than of using them for purposes of solid instruction. This state of things cannot long continue. The impetus which has been given to the study of the physical sciences by the establishment of agricultural and industrial colleges, must sooner or later affect the instruction given in our public schools. Already, in this State, the privilege of free instruction at the Cornell University is held out to the students in our public schools as an inducement to a more diligent use of their opportunities; and, consequently, we may indulge a well-grounded hope that this fact will elevate the standard of education among us, as every boy will seek to place himself where he can receive the most thorough preparation for the competitive examinations which await him.

Another powerful influence will probably be found in the improvement which must sooner or later take place in our civil service. The cases are few in which success in the competitive examinations which must ere long be introduced amongst candidates for positions under government, will depend upon a knowledge of Latin and Greek. Modern languages, mathematics, and the physical sciences are the subjects to which attention must be given if success is to be obtained, and this not only from the direct use to be made of these studies, but from the iufluence which they exert upon the mind.

All these considerations must tend to impress upon the minds of teachers the necessity for thoroughly preparing themselves to take a part in the great work which is approaching. As a slight contribution to this most desirable object, we propose to give a series of articles containing hints on the use of philosophical apparatus, and the best methods of illustrating the principles of natural philosophy. These two subjects are entirely distinct, though often confounded. A lecture or a recitation may be illustrated by a series of experiments, brilliant in the extreme, and faultless in the neatness, accuracy, and success with which they are performed, and yet fail from the fact that the illustrations are either unappropriate or badly arranged—the last cause of failure being the more frequent of the two.

Upon the importance of physical illustrations in a course of scientific instruction it is unnecessary to speak. All successful teachers in this department know that an experiment which can be seen and heard will make an impression upon the minds of the pupils which cannot be equalled by any mere oral or written description. Just think of explaining such a simple matter as a thermometer to a class that had never seen one, and then consider the ease with which it can be done by exhibiting the instrument to

them. What is true of simple instruments is much more true of principles which depend upon unusual phenomena. It would be a very difficult matter to explain to a class the peculiar properties of oxygen or chlorine without illustrating these properties by experiments, and the properties of the air, such as its weight, elasticity, compressibility, etc., are but feebly apprehended by a class who have never seen these properties illustrated by experiments. Most teachers dread the performance of experiments for two reasons: Experimentation is always associated with the idea of "mussiness"—spilt liquids, clothes burned with acids, and general disorder, are, in their minds, the unfailing accompaniments of the performance of experiments. The second reason is the dread of failure.

Dread of failure can be overcome only by certainty of success. Let the teacher feel that the experiments which he is about to perform are *certain* to succeed, and that which was before a dread and an annoyance, will become a pleasure. Nothing is so disheartening as the failure of an experiment. Our whole course of teaching has been an effort to impress upon our students the uniformity of nature and the certainty of obedience to known laws; and now, when we come to test the matter, it is found that either nature is fickle or we do not understand her. The inference against the teacher is, in the minds of most pupils, irresistible, and, of course, it is natural that teachers should dread being placed in such a predicament. The way to avoid this is, not by shirking a duty, but by qualifying ourselves for the performance of it.

As to the first objection, it should be understood that disorder is one of the most efficient causes of failure. Show us an experimenter whose table is in a "muss;" who spills his liquids, knocks over his apparatus, and disturbs his previous arrangements, and we will show you one to whom failure is no stranger. We have now in mind a teacher who often appears upon the lecturer's rostrum, surrounded by apparatus. He, in general, asks and receives very little assistance from those around him. He performs his own experiments, and yet we have seen him, at the close of a lecture involving the use of batteries, jars of liquids and gases, hot acids, furnaces, etc., with scarcely a speck upon his person or a stain upon his clothes. No spilling or overturning with him. He seems to move about among his apparatus as if it were part of himself, and while his lips are giving the most beautiful explanations of physical phenomena, his hands are busily employed in illustrating them. It is needless to say that such an experimenter is "uniformly" successful.

Careful study of the principles involved in the experiment to be performed, combined with a little *private* practice in the necessary manipulations, will soon place any intelligent young man or woman above all dread of failure, and when this is the case, experimenting becomes a pleasure instead of an annoyance.

Cheap Lathes and How to Use Them. IV.

CHOICE OF A LATHE.

THE framing next demands attention. See that it is firm and without shake. If the different pieces can move on each other it will be impossible to do good work. Of course, when the bed or shears are made of one solid piece of metal, all shake of this kind is impossible, so far as this part is concerned, but in the lathes with wooden shears, which consist of two pieces lying parallel with each other, and held together at the ends by means of bolts and screws, it sometimes happens that the bolts get loose, and then there is trouble. Some kind of lock nut would be the best remedy for this. A lock nut is one which, after being screwed up, is *locked*, so that it cannot be unscrewed without special means for loosening it. As these bolts rarely, if ever, require to be taken out after they are once in place, a good plan is to slightly rivet them if they should ever get shaky.

Although metal shears, cast in one piece, cannot get shaky themselves, they are frequently fixed to the frame in such a way as not to be very firm. The top of the frame or support should be broad, and

the fit between it and the shears or bed should be good, otherwise it will be impossible to prevent chattering.

The heads should stand upon long bearings. A bearing of an inch or two is too much like a point, and the back head will be very apt to rock unless the bearing is long.

The back head-stock should fit accurately between the ways or shears, if this is the manner in which it is attached. Of course, where the head-stocks slide on Vs, there is no danger of getting the centres out of line; but if the back head or poppit slides on smooth ways with a tongue dropping down between them for the purpose of guiding it, unless this tongue fits accurately between the shears, the head may easily be skewed round so that the centres will not be in line.

We have already spoken of the spindle and of the necessity for its running true. In order that it may run steadily, it should have considerable length between the bearings.

Some of the cheap lathes in market are wonderful specimens of fancy work, being gilt and painted to an extraordinary degree. Avoid all such. See that the article you purchase is well made and simply finished, but avoid all gewgaws and frippery.

Chucking Work on the Lathe.

BY JOSHUA ROSE, M.E.

WORK held in a lathe otherwise than by being suspended between the lathe-centers, is what is termed chucked. The simplest method of chucking is with a strap—that is a plate of iron bolted across the work. Suppose, for example, that it is required to turn out the hole, A, in Fig. 1, it would if a small piece be placed

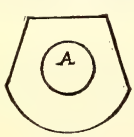

Fig. 1.

against the lathe face-plate, B, in Fig. 2; a plate of iron, C, placed over it, and the bar, D, forced against C by the back or dead centre of the lathe, to hold the work up against the lathe face-plate while chucking it.

Figure 3 shows how the chucking is done. A is the work, B the lathe face-plate, and C the plate or clamp holding

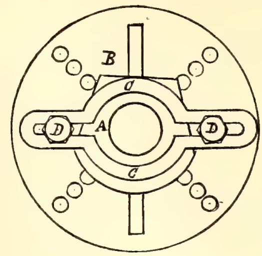

Fig. 2.

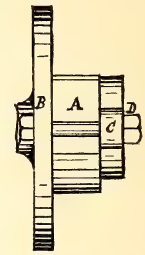

Fig. 3.

the work to B by means of the bolts, D D. An excellent example of chucking by plates is a crank, say for a model steam-engine, such as shown in Fig. 4. In this

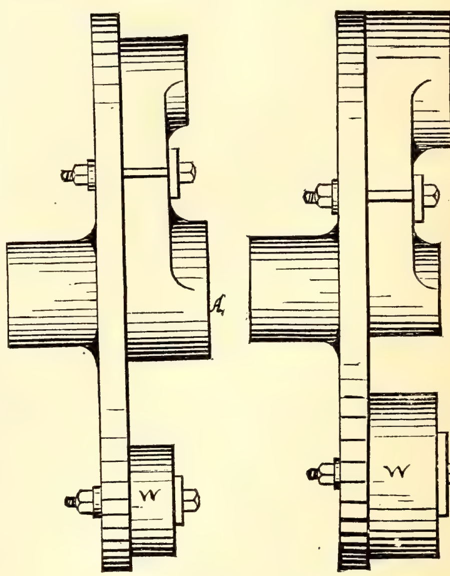

Fig. 4.

case the plate is out of the way, so that the face, A, can be turned as well as the hole bored, hence the face is sure to be true with the hole. The pieces, W, are balance weights to counterpoise the work on the face-place.

Sometimes a projection, such as B, in Fig. 5, prevents the work from going up against the face-plate, and parallel pieces

of iron, A, D, E, are put behind the work, directly beneath the holding plates or

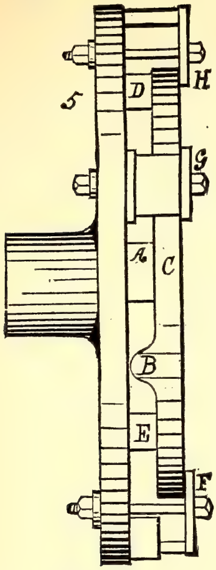

Fig. 5.

clamps, H, F. It should be noticed that the heads of the bolts are outwards; this is because it is difficult to get bolts of just the right length for a piece of work, and

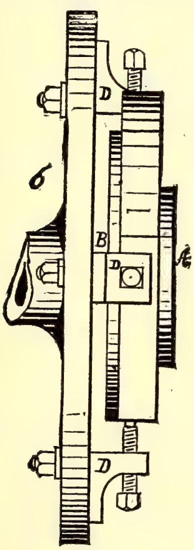

Fig. 6.

it does not matter how far the ends of the bolts project *behind* the face-plate.

If a piece of work requires turning on both radial faces, it is held off the face-plate by what are termed dogs, which are shown at D D, in Fig. 6.

Care of Gold Fish.

In a recent issue of *Vick's Monthly*, Seth Green, whose reputation as a fish culturist is world-wide, gives the following directions for keeping gold fish:

I will tell Miss Nettie how to care for her gold fish. The cause of the fungus growing on the fish is that the slime or scales of the fish had become rubbed off, either by handling or by some other means. If you wish to move your fish from one vessel to another, you should use a net made of some kind of thin, soft material—mosquito netting or an old veil will answer. They should never be taken in the hands. You may not have handled them, but some one else may have done so, either before or after you purchased them. The only cure I know of for the white fungus, is to make a strong brine of common salt and put the fish into it for a minute or two, then immediately put them back into fresh water. Do this three times a day. If you commence doing this when you first discover the fungus growing on them, you will sometimes cure them. When you have healthy fish, keep them well by changing the water every time they come to the top and keep opening their mouths, and seem to be breathing more air than water. When you change the water do so by taking about one-half out at a time and replacing it with fresh—a full change is very apt to prove injurious. Give them plenty of food, such as angle-worms, or any kind of insects, or fresh meat cut into small pieces; fish-wafer is also good. They should have a change of food every week or so.

If you have no plants in your aquarium, I would advise putting in a little fresh earth as often as once a month, and leaving it for two or three days. There should be no food left in the water after it is ten hours old, as decaying meat taints the water the same as it would the air. A fish's nostrils are more sensitive to bad odors than Miss Nettie's, but she would

have the advantage of the fish, being able to run away, whereas, the fish, enclosed in a small aquarium, must stay and take it as it comes.

Now, Miss Nettie, I want you to make a study of your fish, and you will soon learn when anything ails them; you will learn by their actions that something is wrong, and will know it as sure as you know when your own head aches, and if you are as prompt to do something for your fish as you are to do something for your head, your fish will thrive much better. I have a daughter who keeps gold fish for years.

Magic as an Aid in Civilization.

PROBABLY the only instance in modern times in which a conjuror has been called upon to exercise his profession in the employment of Government, was that of Robert Houdin. He was sent to Algeria by the French Minister of Foreign Affairs to exercise the black art in that benighted country, hoping thus to destroy the influence exercised among the Arabs by the Marabouts—an influence which was often mischievously applied. By a few cunning, yet clumsy tricks, these Marabouts passed themselves off as sorcerers, and were held in fear and veneration by the ignorant tribes. The French Government desired to show the Arabs that these would-be leaders among them were mere impostors, and that their pretended supernatural powers were without the least foundation in truth. The best way to do this, it was thought, would be to send one among them who should eclipse their skill, and thus discredit their science and pretended powers. It was resolved to send Robert Houdin, and the wizard was ordered to appear at the Government office in Paris forthwith.

Houdin was a little puzzled to know what the minister could want with him. The plan and purpose of the government were made known to him, and he entered with spirit into the idea and its successful application. With every facility and all needed protection, Houdin sailed for Algeria to astonish the natives. This he succeeded in doing by means of a few striking tricks, of which we shall give a full explanation in our next.

Arriving under favorable auspices, he went at once to work upon the object of his mission, and gaping crowds followed him everywhere, thinking him inspired. He succeeded in showing the people that he could vanquish the famous prophets, who had obtained such control over the ignorant masses of the population, and thus threw them into such discredit that he succeeded in disarming them almost entirely of their influence.

Still, there was one of the Marabouts whom he had not yet met, and who scoffed at the reported powers of this French wizard. A day was therefore appointed when the two should appear before the people, and each give evidence of his own peculiar powers.

One of the great pretensions of the Marabout was to invulnerability. At the moment that a loaded musket was pointed at him and the trigger pulled, he pronounced a few cabalistic words and the weapon would not go off. Houdin instantly detected the trick, and showed that the touch-hole of the musket was carefully plugged. This rendered the Arab conjuror furious, and he, of course, abused his French rival without mercy. Houdin was perfectly cool, and, turning to him, said: "You are angry with me."

"I am," said the Marabout.

"And would be avenged?"

"Yes," he replied, regarding Houdin with eyes gleaming with ferocity.

"It is very easy."

"Show me the way."

"I will show you," said Houdin, quietly, while the Arab was all attention.

"Take a pistol; load it yourself. Here are bullets. Put one in the barrel. But stop—"

"For what?" said the Arab.

"Mark the bullet with your knife, that you may know it." The Arab did as he was told.

"You are quite certain now," said Houdin, "that the pistol is properly loaded."

"Yes."

"Tell me, do you feel no remorse in killing me thus, even though I consent?"

"No!" and the eyes of the savage grew darker with an expression of cruelty.

"It is strange," said Houdin, almost sadly.

"You are my enemy, and I will kill you," he replied.

"Wait but a moment."

Houdin then stuck an apple on the point of a knife, and calmly gave the word, as he held the fruit raised in one hand, "Fire!"

The pistol was discharged, the apple flew far away, and there appeared in its place, stuck on the point of the knife, the bullet which the Marabout had marked. The spectators, though aroused to intense excitement of feeling, remained mute with stupefaction, while the Marabout bowed before his superior, saying:

"God is great! I am vanquished."

Great was the triumph of the French wizard.

Houdin then called for an empty bowl, which he kept constantly full of boiling coffee, though but few of the Arabs would taste it, for they were sure that it was the evil one's coffee pot from whence it came. He told them that it was within his power to deprive them of all strength and to restore it to them at will, and he produced, in illustration, a small box, so light that a child could lift it with the fingers.

And now came their astonishment.

This box suddenly became so heavy that the strongest man could not raise it, and the Arabs, who prize physical strength above everything, looked with terror upon the magician, who, they doubted not, could annihilate them by the mere exertion of his will.

The people expressed this belief, in which the wizard, of course, confirmed them, and promised that, at a day appointed, he would convert one of them into smoke. The day came and the throng was prodigious. A fanatical Marabout had agreed to give himself up to the French sorcerer for the experiment.

The preparations were on a grand scale. The Marâbout was made to stand upon a table, and was covered with transparent gauze. Then Houdin and another person lifted the table by the ends, when the Arab disappeared in a profuse cloud of smoke. The terror of the spectators was indescribable. They rushed out of the place and ran a long distance before the boldest could make up their minds to return and look for the Marabout. They found him near the spot where he had so mysteriously disappeared, but he could not answer their questions; he could tell them nothing at all, and only gazed wildly at them like one bereft of his senses. He was entirely ignorant of what had happened to him.

This was Houdin's closing exhibition in Arabia. The minds of the people had been filled with wonder, and he was venerated by all, while the pretentious Marabouts were in utter disgrace.

Cast a Line for Yourself.

SOME people are lazy, and do not work as much as others, but strive to get what others have. The following incident, which occurred in an eastern State, between a man and a boy, is a very good example of the above.

A young man stood listlessly watching some anglers on a bridge. He was poor and dejected. At last, approaching a basket filled with wholesome looking fish, he cried, "If, now, I had these, I would be happy. I could sell them at a fair price, and buy nice food and lodgings."

"I will give you just as many, and just as good fish," said the owner, who chanced to overhear his words, "if you will do me a trifling favor."

"And what is that?" asked he eagerly.

"Only to tend this till I come back; I wish to go on a short errand."

The proposal was quickly accepted. The old man was gone so long that the young man began to be impatient. Meanwhile the hungry fish snapped greedily at the baited hook, and the young man lost all depression in the excitement of pulling them in, and, when the owner of the line returned, he had caught a large number.

Counting out from them as many as were in the basket, and presenting them to the young man, the old fisherman said: "I fulfil my promise from the fish you

have caught, to teach you, whenever you see others earning what you need, to waste no time in fruitless wishing, but 'to cast a line for yourself.'"

Whistling to a Squirrel.

ONE afternoon last summer, when out looking for game, I sat down on a pile of rails to rest. Pretty soon I discovered in an oak tree, some twenty yards away, a red squirrel stretched at full length on a limb taking a sun bath. Instead of raising my rifle and sending a ball through the little fellow (it's a mighty mean "sportsman" that endeavors to kill all he sees) I decided to give him a little pleasure if I could, so I commenced to whistle the air of that once popular ditty, "I love Thee, Sweet Norah O'Neil." In a twinkling the squirrel was up on his hind legs, his tail over his back, his head cocked to one side, listening to me; a moment of irresolution, and then he scampered down the trunk of the tree to the ground and started towards me; he came a few yards, stopped, sat up on end and listened again. I was careful not to move, and kept on whistling; after waiting a moment, the little beauty came on, jumped up on the pile of rails, ran along within four feet of me, halted, went up on end again, made an umbrella of his tail, tipped head to one side, looked at me with all the gravity of a justice of the peace at his first trial, and yet if ever a creature's eyes beamed with pleasure, his did.

I did not move, but after a little I abruptly changed the tune to the "Sweet By and By." Chut! Why, with the first note of the different tune away went the squirrel. I did not move, only I shook with suppressed laughter, and, as well as I could, kept on whistling. In a minute or two back came the squirrel, going through all the cunning manœuvres of his first approach, and once more took a seat before me on the rails. I watched him, and actually thought he was trying to pucker up his mouth and whistle.

Once again I changed the tune, this time to "Yankee Doodle," and, as before, with the first note of change away scampered the squirrel. Unable to control my risibilities longer, I laughed aloud, and after that I couldn't call my little friend to me.

I wonder how many of the so-called "true sportsmen" ever seek or think of any pleasure in connection with such beautiful little creatures, save the savage and unmanly pleasure of taking away their lives.—*Forest and Stream.*

Common Telescopes.

THE following description of common telescopes, and what may be done with them, is from the advance sheets of Webb's "Celestial Objects for Common Telescopes." The new edition is nearly ready, and will be eagerly sought for by all amateur astronomers.

By "common telescopes" are here intended such as are most frequently met with in private hands; achromatics with apertures* of 3 to 5 inches; or reflectors of somewhat larger diameter, but, in consequence of the loss of light in reflection, not greater brightness.† The original observations in these articles were chiefly made with such an instrument—an achromatic by the younger Tulley, 5½ feet in focal length,‡ with an aperture of 3 7-10 inches, and of fair defining quality; smaller instruments, of course, will do less, especially with faint objects, but are often very perfect and distinct; and even diminutive glasses, if good, are not to be

* "Aperture" always means the clear space which receives the light of the object; the diameter of the object-glass in achromatics, or the large speculum in reflectors, exclusive of its setting.

† Maskelyne estimated the apertures of metallic reflectors and achromatics of equal brightness as 8 to 5. Dawes gives this value for Gregorians, but, like Herschel II., rates Newtonians as 7 to 5. Arago strangely asserted that no light was lost in achromatics; but the effects of absorption and reflection are so considerable, that with very large apertures the advantage of the achromatic disappears. The silver-on-glass specula, invented by Foucault and Steinheil, but perfected in England, take their place between the metal Newtonian and the achromatic, approaching more nearly to the latter, especially when the plane mirror is replaced by a prism (which, however, does not always conduce to critical definition). Buffham assigns equal light to silvered Newtonians of 9, 6⅛ and 4½, and achromatics of 8, 5¾, and 4 inches respectively.

‡ The focal length is measured from the object-glass, or speculum, to the spot where the rays cross and form a picture of the sun or any celestial body.

despised; they will show *something* never seen without them. I have a little hand telescope, 22¼ inches long when fully drawn out, with an object-glass of about 14 inches focus, and 1 1-3 inch aperture: this, with an astronomical eye-piece, will show the *existence* of the solar spots, the mountains in the Moon, Jupiter's satellites, and Saturn's ring. Achromatics of larger dimensions have become much less expensive than formerly, and silvered specula of very considerable size are now comparatively common; even for these it is hoped that this treatise, embodying some of the results of the finest instruments, may not be found an inadequate companion as far as it goes.

In judging of a telescope, we must not be led by appearances. Inferior articles may be showily got up, and the outside must go for nothing. Nor is the clearness of the glass, or the polish of the mirror, any sign of excellence: these may exist with bad "figure" (*i.e.*, irregular curvature), or bad combination of curves, and the inevitable consequence, bad performance. We need not regard bubbles, sand-holes, scratches, in object-glass or speculum; they merely obstruct a very little light. Actual performance is the only adequate test. The image should be neat and well defined with the highest power, and should come in and out of focus sharply; that is, become indistinct by a very slight motion on either side of it. A proper test-object must be chosen; the Moon is too easy; Venus too severe, except for first-rate glasses; large stars have too much glare; Jupiter or Saturn are far better; a close double star is best of all for an experienced eye; but for general purposes a moderate-sized star will suffice; its image, in focus, with the highest power, should be a very small disc, almost a point, accurately round, without "wings,' or rays, or mistiness, or false images, or appendages, except one or two narrow rings of light, regularly circular, and concentric with the image;* and in an uniformly dark field; a slight displacement of the focus either way should enlarge the disc into a luminous circle. If this circle is irregular in outline, or much brighter or fainter towards the centre,* or much better defined on one side of the focus than the other, the telescope may be serviceable, but is not of high excellence. The chances are many, however, against any given night being fine enough for such a purpose, and a fair judgment may be made by day from the figures on a watch-face, or a minute white circle on a black ground, or the image of the sun on a thermometer bulb, placed as far off as possible. An achromatic, notwithstanding the derivation of its name, will show color under high powers where there is much contrast of light and darkness. This "outstanding" or uncorrected color results from the want of a perfect balance between the optical properties of the two kinds of glass of which the object-glass is constructed; it cannot be entirely remedied, but it ought not to be obtrusive. In the best instruments it forms a fringe of violet or blue round luminous objects in focus under high powers, especially Venus in a dark sky: A red or yellow border would be bad; but before condemning an instrument from such a cause, several eye-pieces should be tried, as the fault might lie there, and be easily and cheaply remedied. Reflectors are delightfully exempt from this defect; and as now made, with specula of silvered glass, well deserve, from their comparative cheapness, combined with admirable defining power, to regain much of the preference which has of late years been accorded to achromatics. The horizontal view of objects at all altitudes in a Newtonian reflector with rotating tube is extremely pleasant, when a little experience has been gained in finding and following; the same advantage, however, attends the use of a diagonal eye-piece with the

The real diameter of a star in the telescope would be inconceivably small. The apparent or "spurious" disc, and rings, result from the undulatory nature of light. They seem, however, to be somewhat affected by atmospheric causes. Herschel II. speaks of nights of extraordinary distinctness, in which "*the rings are but traces of rings*, all their light being absorbed into the discs." I have entered 1852, March 23, as "a very fine night, though the rings and appendages around the brighter stars were rather troublesome;" 1852, April 1, "an exceedingly fine night at first, with scarcely a trace of rings or appendages." See also the star 70 Ophiuchi.

*The small mirror in a reflector causes a central darkness out of the focus, which should be nearly the same on either side of it.

achromatic, but with loss of light. The chief disadvantage of reflectors is the greater aperture, and consequently greater atmospheric disturbance, corresponding with the same amount of light; and the occasional renewal of the film causes a little expense or trouble.

The eye-piece, or ocular, is only a kind of microscope, magnifying the image formed in the focus of the object-glass or speculum. The size of this image being in proportion to its distance from the glass or mirror which forms it, the power of the same eye-piece in different telescopes varies as the focal length. Hence the disadvantage of a short telescope; to get high powers, we must employ minute and deeply-curved lenses, which are much less pleasant in use; with a telescope twice as long, half the curvature in the eye-piece produces an equal power. The magnified focal image, as in the camera, is always inverted, and so in the astronomical eye-piece it remains.* For terrestrial purposes it is erected by two additional lenses; but a loss of light is thus incurred, and as the inversion of celestial objects is unimportant, erecting eye-pieces (always the longest of a set) should never be employed for astronomy; the eye soon becomes accustomed to the inverted picture, and the hand to the reversed motion in following the object. The lateral vision in the Newtownian reflector interposes another difficulty, easily mastered, however, by practice, and by attention to the direction of motion through the field. A multitude of eye-pieces is needless, but three at least are desirable; one with low power and large field, for extended groups of stars, nebulæ, and comets, supplying also, if necessary, the place of a "finder" for deep magnifiers; a stronger one for general purposes, especially the moon and planets; and a third, as powerful as the telescope will bear, for minute objects, especially double stars. A greater number of eye-pieces admits, however, of what is often important—an adaptation of the power to the brightness of the object. Ordinary astronomical eye-pieces are shorter in proportion to their power. It is a better plan to change them by means of a short tube, or "adapter," than by a screw; in which case they are more liable to be dropped and injured.

The power may be much increased by unscrewing and and taking away the "field-lens"—that farthest from the eye; but the centre of the field only will be distinct. The highest powers of large telescopes are sometimes made thus, with single lenses for the advantage of light; but the lens is then turned the other way, convex towards the eye, as it gives sharper vision. Sir W. Herschel used the double convex form, as having shallower curves. The common kind, with two lenses, having the flat side of each next the eye, is called the Huyghenian or negative eye-piece: the positive or Ramsden eye-piece has a flatter field, but is not, like the other, achromatic. The interposition of a combination called a Barlow lens raises the power with little loss of light; and as one may be made to suit all the eye-pieces, it doubles the set at a small expense. Brownings's achromatic eye-piece, and Horne and Thornthwaite's aplanatic, and the Kellner construction (for large fields) are all excellent in their way. The brightness of the field varies inversely as the square of the power: and hence minute stars are commonly more visible with deep eye-pieces; the reverse, however, for some unknown reason, sometimes occurs.

If the power of our oculars has not been engraved upon them,* we may get a fair approximation to it by viewing an equally divided scale at a distance (for low powers, a brick wall will answer) with one eye through the telescope, and with the other alongside of it, and noting how many unmagnified divisions are covered by a single magnified image. Or, better still, we may have recourse to the Berthon Power-gauge, a little apparatus, the simple, efficient, and inexpensive character of which entitles it to very warm comendation.

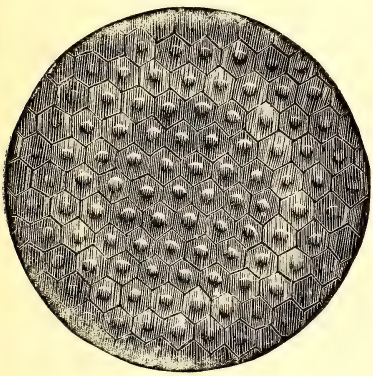
---

*It is erect in the Galilean eye-piece and the Gregorian reflector. But the use of the former is almost confined to opera-glasses, as its field with high powers is exceedingly small; and the latter, an inferior construction, is now little employed.

* These figures are not, however, always to be depended upon, and must be wrong if the eye-piece was made for an instrument of a different focal length. The celebrated Short exaggerated the powers of his reflectors; and those of the great achromatics of Dorpat and Berlin were found by Struve and Encke to be overrated.

How a Fly Sees.

AMONGST the objects which are to be found in every little collection is the fly's eye, so called. On placing it under the microscope, and bringing it into focus, so as to get a clear view, we see an object like a piece of netting, with six-sided meshes. And to most persons this is the end of the fly's eye. They are told that each mesh is a veritable eye, and they believe it, because they have faith in what scientific men tell them. But they have no clear ideas on the subject. If we look at the head of a fly, and particulary that



EYE OF FLY.

of a large blue-bottle or a dragon fly, we shall see that it consists chiefly of two large round lumps, which, under a good magnifier, are seen to be covered with facets, each one of which is an eye, and it is these eyes that under the compound microscope are seen as the meshes of the apparent net. Each one of these eyes transmits a picture or image of all surrounding objects within their scope, but it does not thence follow that the fly sees a thousand faces any more than that we see all objects doubled when we look at them with our two eyes.

To prove that each of these facets is a distinct eye is not a very difficult matter. Those who have good microscopes and a little experience, find no difficulty in showing an image of any object in each facet, so that the whole field of view is filled with little pictures of whatever object may be selected. The most striking object is perhaps a watch face with the second hand in motion. We then seem to see a thousand watch faces, in each of which the seconds are ticked off with the most perfect harmony. To show the watch face clearly requires strong illumination and good definition. In any case, however, the proper illumination of the object is the chief point necessary to secure success. Therefore, it will be found that the easiest object on which a beginner can try his hand is the flame of a lamp or candle. Arrange the microscope in an inclined position, with a 2-3 or 1-2 inch objective, and place a candle or taper below the stage, and about two inches from it. If the microscope be sufficiently inclined the heat and flame will cause no annoyance. The lamp must be in the direct line of the optic axis of the microscope; that is to say, a line passing through the centre of the body of the microscope ought to pass through the flame of the candle. The fly's eye, if now placed on the stage, will be illuminated and may be focussed so as to show the meshes clearly and sharply. If we now move the objective away from the object we will find, after a little while, that we have a distinct view of the flame of the candle in every mesh or facet, and if a breath of air should stir the flame, the hundreds of little flames seen in the field of view will move in precisely the same direction and at the same time.

This is one of the most interesting and instructive microscopical experiments that we know of, and if the reader will study the conditions of success by a little experimenting, he will soon be able to give good exhibitions of the most difficult subjects.

Scientific Amusement.

UNDER this head we propose to give a series of articles containing directions for performing simple but striking experiments in various branches of science. In selecting experiments for this department great care will be taken to choose those only which are entirely free from danger, either to the person,

the clothing, or the furniture, and which are so easily performed that any boy or girl who has a taste for such things need fear no risk of failure.

All the experiments which we shall describe may be performed by means of such ordinary articles as may be found in every household, with the exception of a few pieces, which may be made by any village carpenter or blacksmith, or may be bought for a few cents. We shall give most minute directions for making every piece of apparatus that is used, well-knowing that an experiment which is performed by means of things which we ourselves have got up is far more interesting than those of much greater brilliancy and beauty, which are performed by means of apparatus that has been purchased.

One of the most striking circumstances connected with chemical action is the change which it produces in the condition of bodies. Thus a bar of solid iron, which seems to the ordinary mind one of the most substantial of objects, may be dissolved and rendered not only quite invisible, but imperceptible to the touch. The same is true of a mass of lead or silver, and the following experiments which illustrate this are at once simple and striking.

TO CHANGE A PIECE OF STEEL TO COPPER.

Take a strong solution of sulphate of copper, or blue vitrol, as it was called in olden times, and dip into it a piece of clean and bright iron or steel, such as the blade of a knife. If the surface of the metal is perfectly clean, and, in particular, free from grease, it will, in a few minutes, be *changed* to copper. We use the word "changed" advisedly, for the iron is actually dissolved and the copper takes its place.

A somewhat striking modification of this experiment may be performed as follows: Have a flat piece of polished iron, such as a knife blade, perfectly free from grease, and a sponge or wad of rags soaked in a strong solution of sulphate of copper, to which a very little tartaric acid has been added. On rubbing the iron with the sponge it will be instantly changed to copper.

Song of the Frog.

BY MARY H. WHEELER.

Brothers, brothers in the mire,
Long-tailed tadpoles, frogs entire,
Come up from the mud below!
Hark, again the waters flow!
Hibernating days are o'er,
We may swim and sing once more.

Brothers, brothers, hear my call!
Come up quickly, one and all!
On the banks of pools o'erflowing,
Green, oh! green the reeds are growing,
And the zoospores, set free,
Whirl around and round in glee.

Brothers, lo! the days are long,
Time it is to raise our song!
Twilight, ling'ring in the bogs,
Listens for the voice of frogs.
Shall fair Spring commence her reign
Unannounced by our refrain?

Brothers, of Batrachian race,
From great sires our blood we trace!
But alas! for glory gone
With the labyrinthodon!
Ah! *his* singing was no joke,
Now we only croak and croak.

Brothers, brothers, our hearts still
Feel the great ancestral thrill!
This is why in our veins flow
Blood discs of such size, you know.
But the fugue we sing so late,
Is for race degenerate.

Pittsfield, N. H., April, 1881.

Polishing Vulcanized Rubber.

Remove scratches with a smooth, wet water-of-Ayr stone, and then polish in the lathe with fine pumice and a stiff brush. After washing the pumice off, polish it with whiting and soft brush. The mathematical instrument makers treat it as brass; that is, for flat work they use water-of-Ayr stone, and then rottenstone and oil. Turned work is polished in the lathe with rottenstone and oil, taking care not to use too high a speed, which would heat the work. Some use lampblack and oil to finish with where a very high polish is wanted, or the bare palm of the hand, as in getting up silver plate. Chain and ornament makers use circular buffs for their flat work, made out of sea-horse leather, and for work of irregular forms, buffs of calico. A number of pieces, 12 inches in diameter, are screwed together between flanges, like a circular saw spindle, and used wih rottenstone, always taking care not to heat the work; brushes are not at all suitable for it.

Chrome Ink.

The following recipe is said to have been carefully tested and to have given excellent results: Twenty-four parts of solid commercial extract of logwood, one thousand parts of water, and two parts of yellow chromate of potash; or for a pint of water (a pound, or seven thousand grains), one hundred and sixty-eight grains of the logwood, and fourteen grains of the chromate. Dissolve the logwood in boiling water, filter it, and when cold add the chromate. A little carbonate of soda (a few grains) may be added to prevent the decomposition, which, according to some authorities, is liable to take place in the fluid on exposure to the air. No gum is to be used, as it is not only unnecessary, but injurious. The proportions must be exactly followed, especially in regard to the chromate, any excess of which is unfavorable to the perfection of the ink.

This fluid is of a deep blue-black color when first used, does not corrode steel pens, adheres so firmly to the paper that it may be washed with a sponge or left for hours under water without being dissolved out, and is not easily removed by ordinary chemical agents. It is also one of the cheapest inks that can be made.

Instead of the solid extract of logwood, a saturated solution of logwood may be used (made by boiling the wood in water), but the former, which may be bought of any dealer in drugs and dyestuffs at about twenty cents a pound, is much more convenient.

A Persistent Blue-Bird.

Ed. Young Scientist—One day last summer a male blue-bird came to my window and demanded admission by knocking against the window with his bill, and, as soon as the window was opened, he would fly on the sill and warble a few notes, and then fly away, this he continued for two or three weeks, when he suddenly disappeared, and we saw nothing of him till two or three weeks ago, when he suddenly appeared, and since that time has kept up almost a constant knocking on the windows. I cannot possibly imagine what he wants, except to hide his nest from the English sparrows, which are very numerous here.

ALEXANDER G. GIBBS.

A Powerful Light.

The Brush Electrical Manufacturing Company, at Cleveland, Ohio, has recently manufactured for use in the British navy, an electric light, which has been tested and found to have a 100,000-candle illuminating power—a power 50 times greater than the ordinary electric lamp for street lighting. This is believed to be the largest and most powerful light ever made with human hands. It is designed to be used in night attacks, and to scrutinize the sea for torpedoes. A 40-horse power engine is required to produce the light. The carbons used are two inches and a half thick. The intense heat generated between the carbon points is half a million degrees, one-ninetieth the estimated heat of the sun. It is calculated that with an ordinary reflector a beam of light will be cast so powerful that a person 15 miles away can see to read by it.

Practical Hints.

Pearls.—Set pearls, which have become discolored by wear, may often be improved by placing in a covered vessel with a mixture of whiting, ammonia and water, and permitting them to remain a few hours.

Polishing Powder.—A good powder for cleaning jewelry, silver watch cases, etc., is made by mixing about four parts of whiting with one of rouge, using with alcohol or water; this, it will be found, is easily brushed out of crevices, engravings, etc.

To Solder Tortoise Shell.—Bring the edges of the pieces of shell to fit each other, observing to give the same inclination of grain to each; then secure them in a piece of paper, and place them in hot irons or pincers; apply pressure, and let them cool. The heat must not be so great as to burn the shell; therefore try it first on a white piece of paper.

Liquid Cement.—Equal parts of compound tragacanth powder and powdered gum acacia, (gum arabic,) moistened, according to requirements at the time, with dilute acetic acid, or, if the color will not be of any importance, with ordinary vinegar. This cement is recommended as superior to any that can be bought ready made.

India Rubber Cement.—A good cement, that will render india rubber in any form adherent to glass or metal, may be made as follows: Some shellac is pulverized, and then softened in ten times its weight of strong ammonia, whereby a transparent mass is obtained, which becomes fluid after keeping some little time, without the use of hot water. In three or four weeks the mixture is perfectly liquid, and, when applied, it will be found to soften the rubber. The rubber hardens as soon as the ammonia has evaporated again, and thus becomes impervious both to gases and to liquids. For cementing the rubber sheet, or the material in any shape, to metal, glass, and other such surfaces, the cement is strongly recommended.

EXCHANGES.

Only those who are *yearly* subscribers, and whose names are entered on our books have the privilege of inserting exchanges.

Exchanges must be on separate slips of paper or postal cards. If mixed with business letters or cards they cannot be used.

Exchanges must not exceed thirty words.

Buying and selling belong to the advertising department.

We reserve the right to omit the exchange column, when we have not room for it, and the amount of space at our disposal will regulate the number of insertions given to each *exchange*, the preference being always given to those who have not previously used our columns.

To exchange for offers; a small lot of microscopic mounting apparatus. List on application to J. N. B., Box 1468, N. Y.

To exchange, books and YOUNG SCIENTIST, and trinkets, for other books, revolver, or stylographic pen. Frank Bicknell, Humboldt, Iowa.

Ancient petrified grain, Indian pottery, birds eggs, papers, magazines, Confederate money, fossils, minerals, to exchange for arrow-heads, Indian relics, Confederate, Continental, and other paper money. Fred T. Brinkerhoff, Box 347, Neenah, Wis.

Minerals, tricks, copper coins, book on pigeons and rabbits, Wilson School History, for book on experiments, or specimens, minerals, stamps or coins. P. R. Bradley, Box 305, Dunkirk, N. Y.

Wanted, a second-hand screw cutting foot lathe, must be in good condition; state what is wanted in exchange, also size and make of lathe. G. A. Clark, Castalia, Iowa.

To exchange, minerals, shells, fossil shells, birds eggs, etc., for minerals, shells, fossils, stuffed birds, birds eggs, and books. U. S. Grant, Des Moines, Iowa.

Wanted, botanical correspondents for the coming season, also amateur correspondents in chemistry. L, Box 70, East Templeton, Wov. Co., Mass.

Wanted, to exchange a well-equipped job printing outfit, for books or offers. Frank A. Niblack, Rockport, Ind.

Will exchange for Vol. 2 of the YOUNG SCIENTIST, instructive books bound in cloth to the value of $1.50. Chas. H. Williamson, 293 Eckford St., Greenpoint, Brooklyn, N. Y.

I have a new Munsen's battery, large size, which I wish to exchange for a good revolver or offers. Robt. T. Boyle, 351 West 83d St., New York.

Hair of American deer to exchange for diatoms, foraminifera, or other material. W. H. Osborn, Chardon, Ohio.

To exchange, full instruction in short-hand writing, and birds eggs, for birds eggs, postage stamps, or offers. M. F. E., 51 Spencer St., Albany, N. Y.

"History of Our Country," by Lossing, in six parts, price $15, to exchange for printing press or offers. Frank Chandler, Waverley, Mass.

Fine Devonian and Carb. fossils for others, especially cretaceous fossils, scientific books or papers; Pitman's short-hand works for books or offers. A. Stapleton, East Point, Tioga Co., Penn.

Wanted, scientific books and apparatus; send lists and say what is wanted in exchange. Ewing McLean, Greencastle, Ind.

Wanted, specimens in geology, entomology, oology, etc., for those in other localities, also coins and a charm microscope (magnifies 1,000 times) for one having a different view. J. H. Jones, Frankfort, N. Y.

Send for exchange list of insects, especially Coleoptera and Lepidoptera. Philip Laurent, 621 Marshall St., Philadelphia, Pa.

For printing press or offers, achromatic telescope, $8.50; microscope, $5; set drawing instruments, $3; revolver, $3; Phrenological Journal, $2.50; books, 12 plays, farces, dramas, burlesques, etc., $1.80. F. E. Payne, Alma, Mich.

One pair 3 lb Indian clubs, one scroll saw, one pocket lantern, and a large number of books, for magic lantern, pair telephones, photographic camera, or offers. Thos. A. Black, Lock Box 678, Scranton, Pa.

For exchange, pocket lantern and instruction books for cornet and clarionet; wanted History of the "Franco-Prussian War," and the "Lost Cause." C. W. Hughes, Shreve, Wayne Co., Ohio.

I have Brown's heavy scroll saw attachment, worth $6, which I wish to exchange for a lathe chuck or offers. C. B. Russell, Waterbury Centre, Vt.

Will exchange magnets, electric battery, as good as new, cost £3 in England, for plating battery and materials, or offers. F. Whitehead, Box 55, St. Augustine, Fla.

American and foreign coins to exchange; state what you have. W. J. Allen, 126 Twenty-third Street, Brooklyn, N. Y.

To exchange, fine imported game fowls of the best strain for Fleetwood scroll saw, compound microscope, telescope, magic lantern, shot gun, or offers. E. Alexander, Johnstown, Fulton Co., N. Y. Box 47.

J. T. Bell, Franklin, Pa., has set of ivory chessmen, German flute, six extra keys, value $12, books, etc., to exchange for magic lantern, music box, guns, revolvers, or offers.

Birds eggs and arrow-heads to exchange for fossils and minerals, and birds eggs; send for my list. Clement G. Burns, Salem, Col. Co., Ohio.

Minerals (zeolites, etc.), to exchange for other minerals; state what specimens you have to exchange. H. L. Clapp, 35 West Cottage St., Roxbury, Mass.

Type, in exchange for curiosities, fossils, etc. Geo. K. Fischer, 729 North 6th St., Philadelphia, Pa.

I have some stamps which I would like to trade for stuffed birds, birds eggs and nests; I am also open to an offer; send for list of stamps. A. G. G., Box 26, Summit, New Jersey.

U. S. and foreign postage and revenue stamps for others; U. S. match and medicine especially; send list or sheet and I will do the same. B. M. Hammond, cor. Elm and Live Oak Sts., Dallas, Texas.

To exchange for 1 new Vol. II, Young Scientist, 1 new Vol. I of ditto, and Prof. Bell's Lectures on the Telephone. F. H. Burger, Chester, Pa.

I have 2,000 foreign stamps that I would like to exchange for others. F. Cushing, P. O. Box 178, Wattsburg, Erie Co., Pa.

Wanted, a hand or self-inking printing press, small size, in exchange for books, magazines, papers, etc. B. D. Howell, High Bridge, Hunterdon, Co., N. J.

Demas lathe sea shells, rubber boots, California woods, YOUNG SCIENTIST and paper shells, for stencil dies, boxing gloves, revolver, foils, book on navigation, and manly arts. A. W. Port, San Diego, Cal.

To exchange, an $8 Challenge self-inking printing press, chase 3 x 5 inch, for type or offers. Address, by sealed envelope, Wm. F. Hill, 666 Bergen St., Brooklyn, N. Y.

To exchange, a $60 Wardwell (2 spool) sewing machine, nearly new, also a $3.50 stylographic pen, for coins and books, or offers. C. C. Bulkley, 195 Sigourney St., Hartford, Conn.

An Official Printing Press, must be in good order, and type to make a complete printing outfit; state what is wanted in exchange. W. E. Cushman, Hartford, Ct.

The Young Scientist

SCIENCE IS KNOWLEDGE.

KNOWLEDGE IS POWER.

A PRACTICAL JOURNAL OF

HOME ARTS.

VOL. IV. NEW YORK, JUNE, 1881. No. 6.

Common Telescopes.—II.

THE test of excellence in separating power has been fixed by Dawes at the quotient, expressed in seconds, of 4·56 divided by aperture in inches. Thus a 10-inch object-glass or speculum ought to separate double stars at 0″·456 of distance between their centres. This value practically concurs with those given by Dallmeyer and Alvan Clark. Reflectors somewhat surpass achromatics in this respect, as theoretically they ought to do; but they are apt to be more troubled by rings and flare, and scattered light. The best telescopes of either kind will bear a power of 100 per inch of aperture on stars: for planets, or the moon, half that power will usually more than suffice.

An object-glass of inferior definition may sometimes be improved by stopping out defects, or contracting the aperture. Streaks or specks of unequal density are very injurious; they may be detected by turning the telescope to a bright light, taking out the eye-piece, and placing the eye in the focus; every irregularity will then be visible in the illumination which overspreads the object-glass; and, if of small extent, may be stopped out by a bit of sticking-plaster. If the performance is not thus improved, try a contracted aperture: make a cap of pasteboard fitting over the object-glass like the usual brass cap, but with a circular opening a little less than the clear aperture—if the indistinctness is thus diminished, but not removed, try several discs of pasteboard placed successively within this cap with progressively contracted openings, till distinct vision is obtained; there we must stop, or valuable light will be lost. An eccentric opening in the pasteboard disc may sometimes be serviceable, being turned round the axis so as to expose different parts of the glass or mirror, till the best effect is produced; in other cases, a central pasteboard disc, supported by nar-

row arms from the sides, and leaving an open ring of light all round, may be tried. But for comets or nebulæ, it will be best to restore the original aperture, as with faint and ill-defined objects light is more essential than distinctness. The centering of a reflector is more liable to derangement than that of an achromatic; it is, however, easily rectified by the cautious use of the screws which are provided for the purpose. When in correct adjustment, the eye-piece being removed, a dark spot will be seen in the centre of the small mirror, which is the image of that mirror reflected by the large speculum; in proportion as it deviates from a central position, the adjustment is incomplete, and the performance defective.

The definition of reflectors may often be greatly improved by the use of a tube perforated with large and numerous openings; it is also desirable, where practicable, to interpose between the observer and the instrument, in cold weather, a moveable screen of felt or some non-conducting material.

A good stand is essential; if unsteady, it will spoil the most distinct performance; if awkward, it will annoy the observer; if limited in range, it may disappoint him at some interesting juncture. It may be well left to a respectable optician ; but where expense is a serious consideration, a little mechanical ingenuity and knowledge of such contrivances will devise one which will answer sufficiently. The old arrangement, with a vertical and horizontal, or "altitude and azimuth" motion, is simple and manageable; the equatorial form, which makes the telescope revolve on an axis parallel to that of the earth, has great advantages, in following the object by a single motion, and where the expense of divided circles and spirit-levels is admissible, in finding planets and bright stars by day, and identifying minute objects by night; but, to do its work, it must be placed accurately in the meridian, and out of that position has little superiority. The tube, too, must rotate in a cradle, or the ocular will assume very awkward inclinations. In any case, if the stand is to be movable, let it be strong enough for steadiness without being too heavy for portability.*
